## Abstract

This thesis, entitled "*Procedural terrain generation for underwater environments*", focuses on the topic of procedural terrain generation in underwater environments. Terrain generation is still an open research area in computer graphics because, with the emergence of simulation, rendering, and interaction techniques, the entire field is experiencing increased collaboration with terrain experts. Bringing the physical world into a computer and allowing users to see and manipulate this virtual world helps to better understand it and to bring together numerous experts, gradually breaking down the boundaries of scientific disciplines. Terrain science brings together, in almost a direct manner, geologists, oceanologists, physicists, meteorologists, biologists, roboticists, computer scientists, artists, and more. We focused our work on the inclusion of the user in the generation process through fast and controllable algorithms.

This thesis is divided into three parts, guiding the user from the design of a landscape to its finalization, step by step. Firstly, we will propose a formalization of terrain designing, allowing for the conception of environments in a semantic sense, abstracting away from geometry and data structures.

Secondly, we will see how to give 3D form to these environments. We will propose new algorithms for the generation and modeling of coral islands and karst networks.

In the third part, we will focus on adding realism to 3D terrains through physical simulations of erosion processes. We will demonstrate a flexible and controllable method to imitate the long-term effects of water and wind on both terrestrial and marine landscapes.

**Keywords:** terrain representation, procedural generation, physical simulations, user interaction

# CHAPTER 1

---

## Introduction

---

Over the past 50 years, terrain generation has emerged as an increasingly active domain inside the field of computer graphics. As the demand for more realistic, faster, and automated processes has grown, terrain generation techniques have evolved to meet these challenges. The focus of this work is on one specific branch of terrain generation: the interactive creation and modeling of landscapes.

[TODO]

What sets this work apart is its emphasis on underwater landscapes, an area still overviewed but with an important relevance in marine biology, oceanography, and underwater robotics. Furthermore, the extension of these techniques to new areas of the entertainment industry, such as video games and cinema, presents new opportunities for innovation.

[TODO]

The central question guiding this research is: "How can we efficiently guide the user in the creation of virtual content along the production process line to maintain as much control as possible over the final product?" This concept of "guiding" rather than "replacing" the user is, from my point of view, fundamental, as no machine can truly know better than a human what the final product should look like. The goal is to present algorithms that can be used flexibly within a production pipeline, adapting to any terrain representation, fluid solver, landscape type, hardware, or objective, whether the final use is real-time rendering, realism, or animation.

Maintaining control over the creative process is essential. Each generated result should feel unique, meet the user's expectations, be explainable, and be easily correctible without requiring a complete regeneration. This approach ensures that the user remains at the center of the creative process, with the tools and algorithms serving to enhance, rather than replace, their objectives.

### 1.1 Contributions and outlines

This research follows the chronological order of terrain generation, beginning with the development of an abstract representation that bridges the gap between computer science and Earth science. This approach offers a generalization of the desired landscape type, with a particular focus on underwater environments, but also applicable to terrestrial landscapes.

One of the key contributions is the proposal of new types of landscapes, including karst networks and coral islands, which maintain the notion of sparseness through the use of implicit volumes. Additionally, a new particle-based erosion simulation method is introduced. This method is agnostic to the terrain representation, making it lightweight, fast, and easy to implement. The overarching aim is to provide maximum control to the user, not only during the generation process but also in making corrections to details upstream, ensuring that the final product aligns with the user's vision.

### 1.1.1 Semantics

[TODO] This interdisciplinary approach enriches the modeling process, ensuring that the generated landscapes reflect real-world biological and geological phenomena.

### 1.1.2 Modeling

The generation of certain landscape elements, such as karst networks and coral islands, remains relatively new. While karsts have been explored in previous research (Axel Paris), the representation of coral islands, particularly in the context of Darwin's theories, is an innovative contribution. Karst networks are represented in a highly user-friendly manner, using a directed acyclic graph structure, which closely resembles a tree structure. This method is enhanced by a fractal generation approach with cycles, allowing for iterative generation of complex landscapes. The modeling of coral islands is based on both historical observations and travel journals.

### 1.1.3 Amplification

To increase the realism of the generated landscapes, details are added through a particle-based erosion method. This method is designed to be generalizable for flexibility, and its implementation is oriented towards speed and parallelization.

These contributions collectively aim to advance the field of terrain generation, providing new tools and methods that offer both flexibility and control to users, while also pushing the boundaries of what is possible in the simulation and modeling of natural landscapes.

## 1.2 Procedural generation and terrain generation

Procedural generation is a method used in computer science to create data algorithmically rather than manually, enabling the automatic generation of large amounts of content with minimal human input. This approach is crucial in fields such as game development, where it helps create expansive, varied worlds, and in simulations or data generation where diverse scenarios or datasets are needed. The process typically involves defining rules and algorithms that dictate how content is generated, ensuring it meets specific criteria and patterns, often incorporating randomness through noise functions to produce unique results each time. Incorporating adjustable parameters and customizable rules in the algorithms allows users to influence the characteristics and outcomes of the generated content. This method enhances efficiency, creativity, and scalability in digital content creation, but the main challenges are ensuring the generated content from a single algorithm is both diverse and coherent and achieving a balance between speed, realism and control to satisfy the desired design and quality.

### 1.2.1 Definition

Procedural generation is a powerful technique for creating data algorithmically, rather than manually. This method is extensively used in areas such as computer graphics, simulations, and game development. Essentially, it involves using predefined rules or algorithms to generate complex structures or systems. For example, it can be employed to create landscapes, textures, or even entire worlds.

One of the main benefits of procedural generation is its data independence. The content generated is mainly created in real-time or on-the-fly, rather than being stored explicitly. This allows for the creation of extensive and dynamic content without the need for large amounts of storage space. Another use case of procedural generation take advantage of the diversity of resulting content, allowing to create quickly a large amount of data from which only small improvement has to be made.

In practical applications, procedural generation is commonly used in video games. It enables the creation of vast, varied, and detailed environments efficiently, without requiring extensive storage. This automated approach involves defining a set of rules or procedures that produce diverse outputs, making the content creation process both dynamic and flexible. The generated content can adapt and change in response to different inputs or conditions, which is particularly valuable for applications needing variability and adaptability.

- INCLUDE OTHER USE CASE THAN TERRAIN GENERATION:

\*\* Character animation, level generation, character texturing, ...

\*\* Add examples from games

- INCLUDE CINEMA USE CASES

\*\* Large realistic terrains gen, facial animation, crowd simulation, ... (find other use cases)

- INCLUDE SIMULATION:

\*\* Real-world scenes, environment variable isolation, ...

The integration of algorithms and data is a key aspect of procedural generation. It combines mathematical models, noise functions, and other algorithms to produce both realistic and abstract content. This might involve generating natural features like landscapes or textures, or even entire ecosystems. Incorporating elements of real-world phenomena, such as erosion patterns in terrain generation, can make the environments more believable and interactive.

Moreover, procedural generation allows for user-driven customization. Users can influence or guide the content generation process, leading to user-specific outcomes. This feature, combined with the scalability and efficiency of procedural methods, means that large amounts of data can be produced with relatively low computational and storage costs compared to manually crafted content.

[STOCHASTIC v. DETERMINIST ALGORITHMS]

Rule-based systems are another aspect of procedural generation, using predefined rules to generate content. This approach allows for controlled and structured outputs. Typically, procedural generation involves iterative processes, where initial results are refined or adjusted based on additional rules or parameters.

The advantages of procedural generation include efficiency, as it reduces the need for extensive manual creation, and variability, as it can produce a wide range of unique outputs from the same set of rules. Additionally, it is adaptable, easily responding to changes in requirements or user input, and it minimizes storage needs by generating content on-the-fly.

However, there are challenges associated with procedural generation. The complexity of developing and fine-tuning algorithms can be significant, requiring careful balancing of parameters. Striking a balance between realistic content and computational performance

can also be difficult. Furthermore, meeting user expectations for content quality and variety, especially in interactive applications, can be a challenge.

### 1.2.2 History

Early developments in procedural generation can be traced back to the mid-20th century, grounded in mathematical and algorithmic theories. This period saw the introduction of key concepts like randomness and noise functions, which laid the foundation for procedural techniques. One notable advancement was the introduction of noise functions, such as Perlin noise in 1983. This method allowed for the generation of smooth, natural-looking randomness in computer graphics. [ORIGINAL USE CASE OF PERLIN NOISE + DESCRIPTION OF NOISE FUNCTION]

Building on this, Ken Perlin developed Simplex noise in 1985. Simplex noise represented a significant improvement over Perlin noise by offering a more computationally efficient and visually pleasing alternative. During the same era, fractal geometry emerged, introducing the concept of generating self-similar structures. This had a substantial impact on terrain generation and procedural modeling, providing a new way to create intricate and repeating patterns. [DESCRIPTION OF NOISE FUNCTION]

As procedural generation began to find applications in video games and interactive media, its impact became more pronounced. In 1980, the game "Rogue" showcased procedural generation in its level design, featuring randomly generated dungeons and item placements. This was followed by "Elite" in 1984, which utilized procedural generation to create unique characteristics for each planet of an entire solar system of 2048 planets, such as names, positions in space, economic models, and resource availability, for about 20Ko. This approach contributed to a diverse and expansive game universe, enhancing replayability and exploration.

The evolution continued with significant milestones in procedural content generation (PCG). "Dwarf Fortress," released in 2006, became renowned for its deep and complex world generation, which included detailed civilizations, histories, and ecosystems. "Spore," released in 2008, pushed the boundaries further by using procedural generation extensively, as the game did not store textures, music, or animations. "Minecraft," released in 2011, revolutionized procedural generation in gaming by creating vast, open worlds with a variety of biomes and features. [CITATIONS]

In addition to video games, procedural generation found applications in simulations and computer graphics. For scientific simulations, it was used in terrain generation for geological studies and virtual landscapes, as well as in fluid dynamics to simulate realistic fluid behaviors. In the realm of computer graphics and animation, procedural techniques became essential for creating complex visual effects, landscapes, and textures in films, which would be labor-intensive to model manually. The emergence of real-time graphics and game engines like Unreal Engine and Unity further leveraged procedural generation to create dynamic content and diverse environments.

Computer technology improvements have played a crucial role in the evolution of procedural generation. Improvements in noise functions, such as Worley noise and new variations of Perlin noise, enhanced both the quality and efficiency of procedural methods. Recent developments in machine learning and artificial intelligence have been integrated with procedural generation to produce more complex and adaptive content. The increase in computing power has also been pivotal, allowing for the generation of more detailed and complex procedural content in real time. Additionally, the use of parallel processing and GPUs has accelerated these processes, enabling real-time applications and high-resolution simulations.

### 1.2.3 Models represented

Procedural generation encompasses various models and techniques that create complex and natural-looking content. These models range from mathematical functions to advanced neural networks and physical simulations, each resulting on the generation of diverse and realistic environments.

One foundational technique in procedural generation is noise. Perlin noise, developed by Ken Perlin in 1983, is a gradient noise function designed to produce smooth, coherent patterns that mimic natural phenomena. Its continuous and smooth randomness makes it particularly suitable for generating textures, terrains, and procedural landscapes that appear natural. Building on this, Simplex noise, introduced by Perlin in 2001, offers a more computationally efficient alternative with fewer directional artifacts. It is favored for its improved visual coherence and efficiency in higher-dimensional spaces, making it ideal for procedural texture generation and terrain creation. Another variant of noise, Worley noise creates patterns based on the distance between points in a space. This technique produces cellular structures with distinct boundaries, making it useful for generating textures like stone or marble, and for modeling natural patterns such as cloud formations and cellular structures.

In addition to noise functions, cellular automata provide another approach to procedural generation. These are discrete, grid-based models where each cell evolves according to a set of rules applied to its neighbors. Originating in the 1940s with John von Neumann and Stanislaw Ulam, cellular automata have been used to model complex systems and processes using only few simple rules. They are particularly employed to generate cave systems in video games, but are also used to create various patterns and textures, including forests, vegetation, and city layouts. Notable examples include Conway's Game of Life, which demonstrates how simple rules can lead to complex, self-organizing patterns, and Langton's Ant, which showcases how basic rules can produce diverse and intricate behaviors. The mathematical formalism of cellular automata made it possible to represent real-world phenomena like avalanches, fluids, ... in rules [CITATIONS]. Cellular automata got generalized to continuous time fields, and continuous space fields. [CITATIONS LENIA]

Neural networks represent a more recent advancement in procedural generation. Artificial Neural Networks (ANNs), inspired by the human brain, learn patterns and generate data. Generative models, including Generative Adversarial Networks (GANs) and Variational Autoencoders (VAEs), are designed specifically for content generation. GANs use two neural networks—a generator and a discriminator—that compete with each other to produce realistic outputs. VAEs, on the other hand, encode and decode data to and from a latent space to generate new, similar instances. These models are applied to generate realistic textures, terrains, and photorealistic images, enhancing the detail and variety of content in video games and simulations.

Finally, physical phenomena modeling uses simulations of real-world processes to generate natural features and behaviors. This includes models for fluid dynamics, erosion, sediment transport, and other geological and environmental processes. These models are most often used for improve the realism of terrains than creating them. Terrain features such as mountains, valleys, and riverbeds, as well as environmental simulations that include weather patterns, climate, and natural disaster scenarios can be modeled through simulations. Erosion models, for instance, simulate the effects of weathering and erosion on terrain, using algorithms that mimic natural processes like water flow and wind. Sediment transport models simulate the movement and deposition of sediment, contributing to the realistic formation and evolution of terrain.

### 1.2.4 User interaction

#### Realism-speed-control balance

User interaction affects how users balance realism, speed, and control over generated content.

Realism refers to the extent to which generated content accurately represents real-world characteristics, such as visual details, physical processes, and natural patterns. This is especially important in simulations, visualizations, and training environments where plausibility [FIND BETTER TERM] is critical. Techniques to enhance realism include physical simulations, which model processes like erosion and sediment transport, and the integration of expert knowledge from fields such as geology and ecology. However, achieving realism can be challenging due to the complexity of detailed simulations and the need for specialized expertise, which can demand substantial computational resources and inputs.

Speed is about the efficiency of content generation within acceptable time constraints. While no official categorisation has been set, James Gain proposed to describe levels of speed based on response time:

- Real-time: generation in less than 30 milliseconds, essential for interactive applications like VR environments.
- Interactive: generation in under 3 seconds, suitable for user-driven customization in games and simulations.
- Near-interactive: generation in less than 5 minutes, applicable for larger-scale simulations where some delay is acceptable.
- Long-term: generation that takes longer, often used for precomputed content or offline rendering.

Optimizing speed involves using efficient algorithms and parallel processing. Almost all recent works achieve fast execution time thanks to high parallelisation on GPU. Other types of algorithm may rely on a refinement paradigm, generating a coarse result at first and then iteratively adding finer details, such that the global output shape is available long time before the real final result.

Control refers to how much users can influence or direct the procedural generation process to meet their specific needs or preferences. This includes parameters fine-tuning, allowing users to modify parameters like the noise functions parameters of the simulation variables, and artistic control tools, made for artists and designers to guide the generation process with the use of masks, allowing for combination and mixing of different algorithms.

Challenges in control involve managing diverse and sometimes conflicting user expectations, and balancing the complexity of procedural systems to avoid overwhelming users or producing unrealistic results.

#### Regeneration

The regeneration of procedurally generated models is an issue often overlooked. As the user is almost satisfied with its generation, he may decide to adjust slightly the parameters used. The challenges of the regeneration are multiple: How to let the user explore the parameter space of the model freely? How to ensure that a small change in a variable induce a small change in the result? How to handle the edition from direct manipulations after regeneration? Those question arise directly from the realism-speed-control balance of our procedural models.

Users can manually start the regeneration process to refresh or update a model. This allows the content to reflect new parameters or conditions as specified by the user. The generation speed has a strong influence on the possibility for the user to fine tune parameters as algorithms that can be executed in real-time or interactive-time keep the user active in his work. Long execution times force him to find optimal parameters beforehand in order to create a satisfying model faster than if it was hand-made, which, when not completely explicit, may feel impossible.

The fine-tuning speed can be improved by different strategies:

- Modifications that have a local incidence on the resulting model requires only a local regeneration of the output. Limiting the spatial scope of an interaction is an efficient mean to keep in the same time a way to explore the parameter space of the algorithm while keeping the predictability of the outcome by avoiding global changes from a local edition.
- Live preview of the outcome can be displayed in a coarse computation, allowing to have a rough idea of the result without the full computation.

[TODO]

## 1.3 Terrain representations

A terrain can be represented in various ways, each of them suited for a given application of which we give an brief overview, more details can be found in ( E. Galin et al., 2019).

### 1.3.1 Elevation models

Elevation models are a fundamental approach in terrain representation, widely used in procedural generation due to their simplicity and efficiency. These models define the terrain as a function  $h : \mathbb{R}^2 \mapsto \mathbb{R}$ , where each point in a 2D plane is mapped to an elevation value. This approach is particularly effective for representing terrains where the elevation is the only varying factor, such as hills, valleys, and plateaus, and it is best suited for terrains without complex 3D features like overhangs or caves. While we visualize elevation models in three dimensions, they are mathematically considered two-dimensional functions. In the domain of terrain generation, we will name them 2.5D models.

Elevation models are widely used in industries where large-scale terrain representation is crucial. In video games, they provide the foundation for creating expansive open-world environments. In geographic information systems (GIS) and remote sensing, height fields are used to represent real-world terrain data, offering a practical means of visualizing and analyzing geographical features. The ability to manipulate and control terrain features procedurally makes elevation models a common choice for applications that require efficient terrain generation and rendering.

They offer a powerful method for representing terrains in procedural generation, combining simplicity with flexibility. While they have limitations in representing complex 3D structures, their efficiency and compatibility with existing algorithms make them indispensable in a variety of applications.

## Implicit height fields

Implicit height fields represent the terrain as a mathematical function that provides a height value at any given point in the domain. These functions can be procedural or closed-form expressions, allowing for compact storage and infinite precision in theory. The elevation function allows for easy manipulation of terrain features, making it ideal for generating terrains that require smooth, continuous surfaces. However, the primary disadvantage is the computational complexity involved in evaluating the function, especially for large or highly detailed terrains. The challenge lies in constructing functions that can realistically represent large-scale terrains with complex landforms.

## Discrete height fields

Discrete height fields, or explicit height fields, are one of the most prevalent methods for terrain representation. These models consist of a 2D grid where each cell contains a height value, representing the elevation at that point. Height fields are particularly advantageous because they are simple to implement and are directly compatible with many rendering techniques and hardware, but also due to their closeness with image processing, a domain studied for many decades now.

The main advantage of height fields is their ability to handle large datasets efficiently, providing a balance between memory usage and detail. However, they are limited by their inability to represent terrains with overhangs or caves, as each point on the grid can only hold a single elevation value. Additionally, height fields often require interpolation methods, such as bi-linear or bi-cubic interpolation, to reconstruct a continuous surface from the discrete grid points.

### 1.3.2 Volumetric models

Volumetric models represent a more complex approach to terrain modeling, allowing for the depiction of 3D features that go beyond the simple surface-based representation provided by elevation models. These models capture not only the surface of the terrain but also its internal structure, making them ideal for representing terrains with overhangs, caves, and other subsurface features. Volumetric models are defined by a function  $\mu : \mathbb{R}^3 \mapsto M$ , where  $M$  denotes the material type at any given point in 3D space. This allows for a detailed representation of the terrain's internal composition, which can be crucial for applications requiring realistic geological simulations.

Volumetric models, including layered materials, voxel grids, and implicit models, are essential in applications where terrain complexity and detail are primordial. In geological simulations, these models allow for accurate representation of subsurface structures and processes. Voxel models are widely used in games that require dynamic terrain deformation, providing a rich interactive environment for players. Implicit models are favored in situations where smooth, continuous surfaces are needed [FIND OTHER USE CASES].

## Function volumetric models

Implicit models represent the terrain using an implicit surface, which is defined as the zero-level set of a continuous field function  $f : \mathbb{R}^3 \mapsto \mathbb{R}$ . The terrain surface is the set of points where this field function equals zero. This approach allows for the smooth representation of complex 3D shapes and is particularly well-suited for modeling continuous, organic structures like rolling hills, caves, and natural arches. Implicit models are flexible and can

represent terrains with overhangs and tunnels, which are challenging for height field-based models.

One of the key advantages of implicit models is their ability to produce smooth surfaces without the need for discrete polygonal meshes, which can result in realistic and natural-looking terrains. However, the computational complexity of evaluating the implicit function, especially for large terrains, can be a significant drawback. Additionally, converting an implicit surface into a mesh for rendering can be challenging and resource-intensive.

### Layered models

Layered models are a type of volumetric representation that encode different material layers within the terrain. Each layer is defined by its thickness or elevation, and multiple layers can be stacked to represent complex geological formations. These layers might include materials like bedrock, sand, soil, or water, each contributing to the overall structure of the terrain. Layered models are particularly useful in simulations that involve processes like erosion or sedimentation, where the interaction between different material layers affect the physical process.

The primary advantage of layered models is their ability to represent a stratified terrain with distinct material properties, which can be manipulated individually. This makes them well-suited for simulations that require detailed geological accuracy. However, they are more complex to implement than simple elevation models and require additional computational resources to manage the interactions between layers.

### Voxel grid models

Voxel grids are a common method for representing 3D terrains in procedural generation, offering the ability to capture complex internal structures and features that are difficult or impossible to represent with surface-based models. In a voxel grid, the 3D space is divided into a regular grid of small, cube-shaped elements called voxels (volumetric pixels). Each voxel holds information about the material or properties of the terrain at that specific point in space. This approach allows for detailed modeling of features such as caves, tunnels, overhangs, and intricate underground networks. The regular grid structure allows for the use of image processing-oriented algorithms.

There are two primary types of voxel grids used in terrain representation: binary voxel grids and density voxel grids. Each has distinct characteristics, advantages, and limitations, making them suitable for different applications. Binary voxel grids are the simplest form of voxel representation. In these grids, each voxel is either "filled" or "empty," representing the presence or absence of material. This binary state is typically represented by a 1 (filled) or 0 (empty). Binary voxel grids are straightforward to implement and require much less memory compared to more complex voxel representations, making them ideal for applications where the primary concern is whether a space is occupied or not.

The simplicity of binary voxel grids is one of their main advantages. They are easy to understand and visualize, with each voxel requiring only a single bit of information to represent its state. Additionally, because only a binary state is stored, these grids can be memory-efficient when combined with compression techniques like Sparse Voxel Octrees (SVOs). The simplicity of the data structure also allows for quick processing, making binary voxel grids suitable for real-time applications where performance is required. However, the binary nature of these grids limits their ability to represent variations in material density or properties, or even smoothness, resulting in less detailed terrain models. This can lead to

hard, blocky edges in the terrain, which may appear unnatural without additional smoothing or processing.

Binary voxel grids are commonly used in applications where simple occupancy information is sufficient. For example, voxel-based games like Minecraft utilize binary grids to create terrains composed of solid blocks with clear boundaries. These grids are also employed in scientific simulations where the primary concern is the presence or absence of materials, rather than detailed material properties. [TRANSFORM TO MATERIAL-VOXELS]

On the other hand, density voxel grids allow each voxel to store a range of values, representing varying degrees of material presence. Instead of a simple binary state, a density voxel grid assigns a scalar value to each voxel, which can represent material density, opacity, or other properties. This added complexity enables density voxel grids to represent subtle variations in terrain, such as gradual changes in material density or smooth transitions between solid and empty spaces, allowing for more realistic and natural-looking terrain models.

Density voxel grids are often used in high-fidelity simulations where detail and realism are essential. They are found in applications such as medical imaging, scientific visualizations, and advanced terrain modeling for films and visual effects. These grids are also employed in procedural terrain generation systems that require smooth and natural transitions between different terrain features, such as caves, cliffs, and eroded landscapes.

### 1.3.3 Existing terrain generation techniques

Procedural generation techniques in terrain generation involve creating terrains using algorithms that do not directly simulate physical processes but instead rely on mathematical models to produce realistic landscapes. These techniques are often phenomenological, focusing on reproducing the observable effects of natural phenomena like erosion, tectonic activity, and sediment deposition. The primary advantage of procedural generation is its ability to create detailed, expansive terrains with relatively little data, often without relying on real-world exemplars.

Procedural terrain generation methods can be broadly classified into two categories: large-scale terrain generation and procedural landform generation. Large-scale terrain generation techniques focus on creating entire terrains over extensive areas, emphasizing fractal and self-similar properties to ensure that details appear consistent at various scales. These methods often offer limited direct control over the specific features of the terrain, as they are primarily concerned with creating natural-looking landscapes across large domains. Examples of such methods include subdivision schemes, faulting, and noise-based techniques, each of which brings a different approach to refining and detailing the terrain.

#### [CITATIONS]

Subdivision schemes iteratively refine an initial coarse terrain by subdividing it and adding detail, often guided by fractal principles. A well-known method is the diamond-square algorithm, which can produce terrains with fractal characteristics but may introduce unwanted artifacts such as local extrema. To mitigate these issues, alternative schemes like the square-square method, which uses a mix of triangle and square subdivisions, have been developed to maintain geometric consistency and reduce artifacts. However, these methods are still prone to producing directional artifacts, requiring further refinement through modified algorithms.

Faulting is another procedural technique that begins with a flat terrain and adds random vertical faults, displacing points on either side of the fault line based on their distance from it. This method is effective in simulating the effects of tectonic activity on terrain formation.

The terrain's elevation is determined by summing the contributions of multiple faults, with random coefficients controlling the magnitude of displacement. The use of smooth step functions ensures that the transition between displaced and non-displaced areas is gradual, creating realistic fault lines. However, this technique requires careful selection of faults to maintain terrain consistency and avoid excessive or unnatural elevation changes.

Noise functions, particularly fractional Brownian motion (fBm), are foundational in procedural terrain generation, used to introduce turbulence and multi-scale effects that mimic the appearance of natural landscapes. By summing noise at different scales and amplitudes, these functions create terrains with a variety of features, from gentle rolling hills to rugged mountains. Specific noise functions, such as ridge noise, are designed to generate sharp features like crests and ridges, while multi-fractal noise allows for non-uniform fractal properties, enhancing the realism of the terrain. Warping techniques, such as domain warping, are applied to avoid grid artifacts and simulate erosion effects without resorting to full physical simulations, further refining the terrain's appearance.

Procedural landform generation techniques, in contrast, focus on the creation of specific terrain features like rivers, cliffs, and canyons. These methods operate on a smaller scale and provide more direct control over the resulting shapes, allowing for targeted synthesis of particular landforms. Controlled subdivision [CITATION], for example, enhances traditional fractal methods by incorporating user-defined features like river networks into the terrain generation process. This approach can be extended to simulate planetary-scale watersheds, ensuring that the generated terrain adheres to the desired topological and hydrological characteristics.

Feature-based construction techniques allow users to define terrain features through interactive sketch-based interfaces, where control curves determine the shape and extent of the landforms. These curves guide the multi-resolution deformation process, ensuring that the terrain conforms to the sketched profiles. By blending different types of curves, such as elevation and cross-sectional profiles, detailed and complex landforms can be created. Procedural generation is used to add fine details like layered terraces and isolated mesas, while shortest-path algorithms help define natural river trajectories.

[TODO]

Procedural generation techniques offer a powerful and flexible approach to terrain generation, allowing for the creation of vast, detailed landscapes with minimal input data. However, these techniques also present challenges, particularly in balancing realism with computational efficiency. While large-scale methods excel at creating expansive terrains with fractal properties, they often lack the direct control needed to generate specific landforms. Conversely, landform generation techniques provide greater control but may require more computational resources to achieve the desired level of detail. The complexity and realism of a process is then defined by the mix of the different algorithms possible in order to create large terrains with realistic landforms.

### 1.3.4 Underwater landscapes

In the field of terrain generation, particularly when it comes to modeling underwater landscapes, the challenge is to accurately represent complex environments that include both geological and biological features. The underwater world is filled with diverse structures, ranging from vast coral reefs to intricate cave systems, each requiring specialized techniques to model their unique characteristics.

### 3D Data for underwater landscapes

One of the most challenging aspects of underwater landscape modeling is capturing the complexity of coral reefs. These environments feature highly intricate 3D structures, including branching corals, coral mounds, and encrusting forms. These formations are not just surface-level features; they extend into the terrain with voids and cavities, such as caves, grottos, and karst networks, which add layers of complexity to their representation. Accurate modeling of coral reefs demands that the porous and irregular nature of these formations is represented in high detail, which is a significant challenge due to the variability of their structures.

In addition to biological features, underwater landscapes are shaped by geological processes that must also be accurately represented. For example, sedimentary layers and underwater geological formations like seamounts and ridges are important components of the terrain. Furthermore, volcanic activity, including underwater volcanoes and hydrothermal vents, significantly impacts the landscape and ecosystem, necessitating their inclusion in any comprehensive model of underwater environments.

To gather the data needed for such detailed modeling, advanced measurement techniques are employed. Sonar, including multi-beam echo sounders, and LIDAR (Light Detection and Ranging) are commonly used to capture detailed 3D data of underwater terrains. These technologies allow for the mapping of areas that are otherwise difficult to access, providing the foundational data necessary for accurate terrain generation. Remote sensing technologies also play a major role, enabling the collection of data over large and remote areas, further enhancing the model's accuracy.

### Interdisciplinary data integration

Accurately modeling underwater landscapes requires more than just geological data; it necessitates an interdisciplinary approach that integrates biological and ecological data. Geological validation is an important step in this process, involving collaboration with geologists and marine scientists to ensure that the models are not only scientifically accurate but also reflective of real-world conditions. This validation process ensures that the generated models accurately depict the geological and biological features present in underwater environments.

Biological data is also essential, particularly when modeling coral reefs and other marine ecosystems. Incorporating data on coral species, marine biodiversity, and ecosystem dynamics allows for the creation of realistic and biologically accurate representations. Additionally, the impact of biological processes, such as coral growth patterns and marine erosion, must be considered, as these factors significantly influence the terrain shape over time.

However, one of the major challenges in modeling underwater landscapes is the scarcity of high-resolution data, especially in remote, protected or less studied areas. This data scarcity makes it difficult to create detailed and accurate models. Another challenge lies in the integration of diverse data types, geological, biological, hydrological, etc, into a cohesive and comprehensive model. Effective integration requires complex techniques to ensure that all aspects of the underwater environment are accurately represented.

### Multi-scale modeling

Underwater landscapes are characterized by features that vary greatly in scale, from vast underwater mountains and ridges to small-scale elements like individual coral polyps and marine vegetation. This diversity in scale necessitates multi-scale modeling techniques that can accommodate both large and small features within the same model.

Large-scale features, such as underwater mountains and ridges, define the macrostructure of the landscape. These must be integrated seamlessly with micro-scale features, such as detailed sedimentary textures and small coral formations, to ensure that the terrain is represented accurately across different scales.

One of the key techniques used in multi-scale modeling is level of detail, which involves adjusting the level of detail in the model based on factors like user interaction or viewing distance. Adaptive LOD techniques help balance the need for visual fidelity with the performance demands of rendering complex terrains. The goal is to preserve detail across scales, ensuring that both macro and micro features are represented without losing important details when the model is scaled or zoomed.

Visualization techniques also play a crucial role in representing underwater landscapes accurately. Hydrographic mapping is one such technique, providing specialized methods to visualize underwater features clearly. Additionally, the use of textures and lighting that simulate underwater conditions, such as light absorption and scattering, enhances the realism of the model. These techniques help create visually accurate and scientifically meaningful representations of underwater environments.

The procedural generation of underwater landscapes involves the integration of advanced 3D data collection techniques, interdisciplinary collaboration, and multi-scale modeling approaches. The unique challenges of modeling underwater environments, ranging from the complex structures of coral reefs to the accurate representation of geological and biological features, require new solutions that combine geological plausibility with visual realism.

## 1.4 Coral reefs (biological aspects)

[BLA BLA BLA TODO]

## 1.5 Fluid simulations

Fluid simulations are inevitable in representing natural phenomena in terrain generation, particularly in modeling water flow, erosion, and sediment transport. These simulations are used for creating realistic and dynamic environmental models that accurately reflect the interactions between fluids and terrain. The ability to simulate fluid behaviors such as river currents, coastal erosion, and sediment deposition is fundamental to producing realistic terrains.

Fluid simulations can be categorized into various methods, each with its unique applications. Techniques like Particle-In-Cell (PIC), Fluid-Implicit Particle (FLIP), and Stable Fluids are commonly used to simulate fluid dynamics. PIC combines particles with a grid to offer a straightforward approach for basic fluid simulations and visualizations. FLIP builds on the PIC method by enhancing accuracy and efficiency through a hybrid approach that merges particle and grid techniques, making it suitable for complex fluid behaviors. Stable Fluids, a grid-based method, is designed for simulating stable, incompressible fluids with minimal computational complexity, often used in interactive applications where real-time rendering is required.

More sophisticated methods include Smoothed Particle Hydrodynamics (SPH) and Marker-And-Cell (MAC). SPH is a particle-based method where fluid properties are represented by particles that interact based on smoothing kernels, useful for detailed simulations, including interactions between fluids and terrain. MAC and other grid-based approaches use

a grid to simulate fluid behavior, providing detailed and accurate representations suitable for various scales of environments. Hybrid methods combine the strengths of grid and particle approaches, balancing the need for detail with performance requirements in complex simulations.

Fluid simulations are integral to terrain representation, particularly in modeling erosion and sediment transport. These simulations allow for the realistic modeling of erosion processes, which affect terrain features like riverbeds and valleys over time. By simulating how fluids interact with the terrain, these models can show how sediment is moved and deposited, contributing to the natural evolution of the landscape. Water flow and hydrology are other applications of fluid simulations in terrain generation. Simulating surface water dynamics, such as the flow of rivers, lakes, and wetlands, helps create realistic environments where water interacts dynamically with the terrain.

Despite their importance, fluid simulations come with significant challenges and considerations. One of the primary concerns is the computational resources required to run accurate and detailed simulations. Performance trade-offs are often necessary, especially in real-time applications where the simulation must balance accuracy with computational efficiency. Complex 3D fluid simulations require powerful hardware, including advanced processors and substantial memory, to handle the intensive calculations involved.

Another challenge lies in balancing accuracy with realism. While detailed fluid dynamics can produce highly realistic simulations, they often come at the cost of performance. Simulation artifacts, or inaccuracies, can also impact the perceived realism of the terrain, requiring careful attention to detail in the modeling process. Integrating fluid simulations with terrain models presents its own set of challenges. Ensuring that fluids interact seamlessly with the terrain, such as through fluid erosion or sediment deposition, requires sophisticated techniques to maintain consistency between the simulated fluid behaviors and the terrain features.

Recent developments in fluid simulation technology have focused on enhancing both the accuracy and efficiency of these simulations. Advancements in algorithms have led to new techniques that improve the realism and computational performance of fluid models. There has also been significant progress in real-time fluid simulation, with innovations aimed at improving interactivity.

The integration of Deep Learning and Machine Learning into fluid simulations represents a recent trend in this field. AI-enhanced simulations use machine learning to refine fluid simulation accuracy and adaptivity, enabling more realistic and responsive environments. Predictive models, powered by AI, can simulate complex fluid behaviors based on historical data, offering new possibilities for dynamic and evolving terrain representations.

## 1.6 Prototype creation

- C++23 and Qt5.12
- OpenGL 4.6 and GLSL
- Marching Cubes on geometry shader
  - \*\* Bad idea, but justify why
- Renderings:
  - \*\* With the prototype:
    - \*\*\* Marching Cubes on geometry shader
    - \*\*\* Triplanar texture
    - \*\*\* Real-time results

\*\*\* Textures based on materials  
\*\* With Unreal Engine 5:  
\*\*\* Static meshes  
\*\*\* Added procedural vegetation with plugin [PLUGIN NAME] and ocean with [PLUGIN NAME]  
\*\* With Blender 4.1:  
\*\*\* Static meshes  
\*\*\* Easier script usage

Figure 2.1: Our method can produce different scenes including coral islands and canyons at multi-scale using Semantic Terrain Entities to represent terrain features.

## 2.1 Introduction

Topographic maps are very useful tools for biologists, geologists or even oceanologists (which would call them "bathymetric charts"). These maps are displayed in 2D but provide 3D information about the altitude (or depth), but can also use symbology to represent the important elements that need to be visible. Map symbols are important in order to extract as much information as possible from a 2D object. In cartography, map symbols are defined as geometric primitives such as points, polylines, polygons, and (rarely) polyhedrons. These symbols are a simplification of the content of an environment, or an abstraction of the 3D shape of the terrain features. This is useful to understand the relationship between the different features, which enables to deduce rules in the evolution of a terrain.

In such way, geologists can study the distribution of peaks in a mountain range, the location of soil types in an area, which in turn allow to deduce possible locations of karst networks, for example. Using the same tools, a biologist may interpret the effect of natural or artificial reefs on coastal erosion, or understand better the interactions inside an ecosystem. Oceanologists may deduce the formation of canyons and fans from old river systems.

The abstraction of the details on the surface allows to focus on the undepth understanding of a process, which may be generalized to different terrain configurations.

Parallelly, terrain artists most of the time sketch the global shape of the terrain they will model beforehand, such that they can check before the modeling part that the consistency and plausibility of the terrain will be valid. Looking at a simplified map before starting the modeling step allows the designer to modify the overall shape of the terrain, at a large scale, before the 3D geometry comes in play, generating too much control points or vertices to be able to deal with.

Starting from an initial configuration or providing conditions on the desired output terrain, the algorithm we propose will let the different terrain features evolve as a multi-agent system, allowing for a simulation of evolution on multiple years, while, at any time, the user can apply modifications or new constraints on the state of the environment. The resulting configuration is an environment conform to the constraints shared by the user, which can be about the number of years of simulation and/or the distribution of features present in the scene.

As described in the previous chapter, most terrain generation algorithm use the geometry of an initial terrain surface to iteratively apply changes such as erosion simulation. While information about some environment variables or properties of the ground may influence the result of an algorithm, the control of the global shape of the terrain is lost as it treat locally the surface, without knowing which feature a certain point on the surface lies on.

The question which led to our solution is the multi-scale user interaction: "Is it possible to provide an interaction mean for terrain generation allowing the user to interact with a small structure like a rock in the same manner as with a large structure like a mountain?". In this work, we want the user to be able to have a large scale representation of the terrain in order to generate a landscape that satisfies his needs while keeping the possibility to apply large modifications. In discussion with robotician users, we realise that we want to create a large landscape that can contain interesting , select a smaller region that have features in a disposition that. In the optic of generating a large scale terrain in which we could focus the generation effort in a certain region, we wished to be able to see a coarse representation that can be computed quickly.

We want this method to be adapted for terrains above and under the water level.

Because many geographical terms would become ambiguous in computer science terms, in which this thesis lie in, we will translate some vocabulary in a way that may be disapproved

by geologists, but we are doing our best to keep it as acceptable for each field as possible.

## 2.2 Related works

Procedural terrain generation has been heavily studied for the last 40 years ( E. Galin et al., 2019). Researches in this topic try to find new solutions to compromise between realism, user control and efficiency ( Gain et al., 2009). Using fractal noise parametrized to resemble real landscape has been an important first step ( Musgrave et al., 1989) as it's a fast and light solution to generate procedurally the appearance of mountains. The lack of user control pushed newer works toward the use of controlled noise by including real DEM in the process through learning ( Brosz et al., 2007; Kapp et al., 2020), while the rise of deep learning technologies gave higher control to the user through sketches ( É. Guérin et al., 2017; Talgorn and Belhadj, 2018).

By including expert knowledge of tectonic process and subsurface geology, some algorithms tend to get more realistic ( Cortial et al., 2019; Michel et al., 2015; Patel et al., 2021).

While these algorithms are able to generate large-scale landscapes, the finer details of the terrain is often computed by the use of erosion simulation ( Cordonnier et al., 2023; Paris et al., 2019b; Schott et al., 2023). This process can be expensive in time but results in more plausible surfaces.

All the algorithms aim to reproduce plausible relief in terrestrial landscapes, mostly limited to alpine landscapes, but a lack of research can be found in almost all other biomes. Underwater landscapes generation, for example, has been almost completely absent from literature for many reasons: the difficulty of accessing the area, the lack of visibility under water and the complex physics of underwater geology and biology make the algorithms adapted for this environment scarce.

The majority of the ocean floor can be represented as a fractal terrain ( Mareschal, 1989). While stochastic noise can be sufficient to model the ocean floor, this process won't cover areas with the biggest biomass, near shallower waters such as near coasts and islands.

Due to the impossibility to observe the large-scale and the small-scale of underwater environments, some works related to geology model large structures like the profile shape of the coral reef ( BOSSCHER and SCHLAGER, 1992), simulate its surface growth ( Li, 2021), or use procedural algorithms for single polyp ( Abela et al., 2015). We however don't have a mix of the different scales, and neither methods take into account the environment such as the topography or the interaction of different terrain features. This is mainly due to the fact that the evolution time for each scale varies from a span of weeks to thousands of years.

In an ecosystem, any element of the system has an impact on their surrounding. Simulating each physical properties such as shading, heat, humidity may require enormous computation power. By considering these properties as scalar fields surrounding the whole scene, and that features of the terrain affect locally the scalar fields, we can simplify the computation of the physical properties of the environment ( Grosbellet et al., 2016; É. Guérin et al., 2016). This process provides a scalable system from which scene details are rendered in a plausible way. In a similar way, other works represent the wind flow as a composition of local vector fields ( Wejchert and Haumann, 1991), avoiding complex fluid simulation while providing user control in a lightweight model. We extend these works by incorporating a time-evolution system such that the scene can be dynamic.

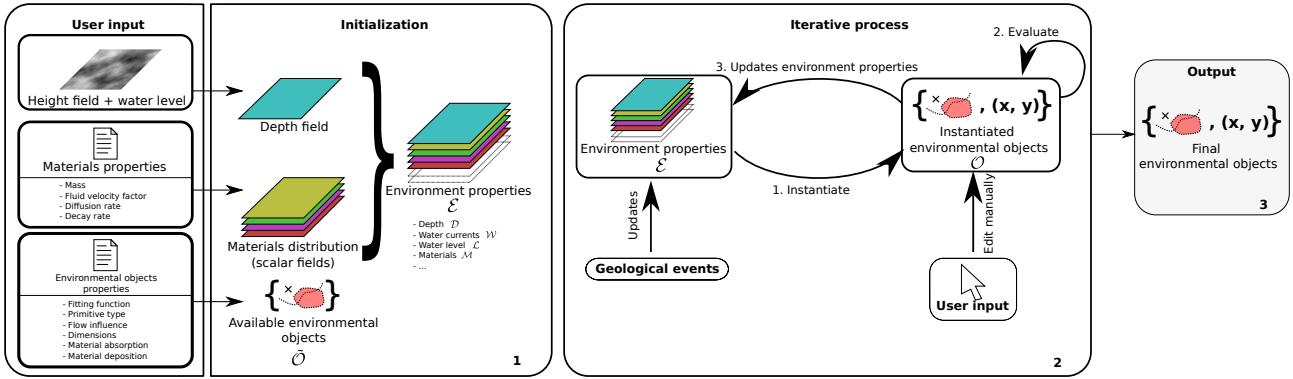

Figure 2.2: Overview of the pipeline of the method. The user provides as input an initial height field and sets the water level, as well as a definition of the environmental modifiers properties and Semantic Terrain Entities properties that will be used in the iterative process. These inputs are initialized as an initial set of Semantic Terrain Entities and scalar fields that represents the environmental attributes. In the iterative loop, new Semantic Terrain Entities are instantiated using the current state of the environment at their optimal position. The existing Semantic Terrain Entities in the terrain reevaluate their fitness function to grow or die and update the environmental attributes locally. At each iteration, geomorphic events can update the environmental attributes, while the user can interact directly with the Semantic Terrain Entities. The result of the whole process is a set of Semantic Terrain Entities which is a sparse representation of the features of the scene.

## 2.3 Overview

The generation of the terrain is initialized using an initial height field  $\mathcal{H}$  and a water level  $\mathcal{L}$ . The height field provides variation on the depth  $\mathcal{D}$ , which can influence the generation process of the scene. We set  $\mathcal{D} = \mathcal{H} - \mathcal{L}$ .

The list of available Semantic Terrain Entities  $\tilde{\mathcal{S}}$ , representing the different features that can be present in the scene, are provided with their properties: type, size, generation rules, growing conditions and effects on the environmental attributes (Section 2.3.2).

Finally, different environmental modifiers can be defined with their properties such as diffusion speed, mass, damping factor and influence from the water currents. Environmental modifiers distributions are represented as a scalar field  $\mathcal{M} : \mathbb{R}^2 \mapsto \mathbb{R}$  and water currents as a vector field  $\mathcal{W} : \mathbb{R}^2 \mapsto \mathbb{R}^2$  that can be evaluated by the Semantic Terrain Entities of the scene to simulate their growth and spawn at the most probable position. The environmental properties  $\mathcal{E} = (\mathcal{D}, \mathcal{W}, \mathcal{L}, \mathcal{M})$  is composed of depth, water currents, water level and environmental modifiers distribution information at any point of the terrain (Section 2.3.1).

The definition of Semantic Terrain Entities' properties and environment properties is done with field experts, providing the pertinent parameters required to model the evolution of the terrain features using expert knowledge (Section ??). Additional properties can easily be added to the environment properties  $\mathcal{E}$  in order to fit to the experts needs, such as atmospheric pressure, humidity, temperature, ...

The generation phase can optionally be started with an initial set of Semantic Terrain Entities present in the scene.

Once the initialization phase is done, the generation begins. The generation process is incremental and its main loop is composed of two different steps: the instantiation of new Semantic Terrain Entities then the update of the environment.

At each iteration, new Semantic Terrain Entities can be created at their most fitting locations if possible. The generation rules provided in the initialization phase are used to find the optimal position from stochastic sampling (Section 2.4). All Semantic Terrain Entities are evaluating their state analytically using the fitness function provided as input (Section 2.4).

Once the instantiation step is done, the environment's values are updated by each Semantic Terrain Entity by depositing and absorbing some of the available environmental modifiers (Section 2.5) while modifying the water currents (Section 2.5.1) around them. Finally, water currents and height field's gradient displace environmental modifiers of the terrain at each iteration. During the generation process, the user can alter directly the distribution and shapes of the Semantic Terrain Entities (Section 2.6.1) and perturb the generation process by planning geomorphic events that have impacts on the environmental attributes (Section 2.6.2).

The output of our system is a set of Semantic Terrain Entities disposed in the plane. We do not provide the 3D representation of the Semantic Terrain Entities, letting the user define the rendering method. The figures used in the paper use a mix of implicit surfaces and triangular meshes.

### 2.3.1 Environmental attributes

In geography, a "field" refers to a continuous spatial phenomenon across a region where each point has a specific value of a variable, unlike discrete objects with distinct boundaries. Fields can be scalar, representing a single value at every point (like temperature or elevation), or vector, representing quantities with magnitude and direction (like wind velocity). Examples include topographic fields for elevation, climatic fields for temperature or precipitation, and magnetic fields for magnetic forces. Fields are mathematically modeled using functions and represented in Geographic Information Systems (GIS) as raster data, where a grid of cells captures continuous variations. This representation is essential for studying spatial patterns and processes such as climate change and resource distribution. Because of the ambiguous nature of the term "field" in mathematics and computer science, we will define the geographic fields as environmental attribute.

In an ecosystem simulation, each actor of the ecosystem has an impact on all other actors, which results in an exponentially growing computation effort as the number of elements of the terrain increase. We avoid this problem by considering the environmental attributes as a proxy to allow any Semantic Terrain Entity to interact with any other one. Each of the Semantic Terrain Entity have a local impact on the environmental attributes without knowledge of neighboring Semantic Terrain Entities. This modification of the environmental attributes are presented as the effect of environmental modifiers defined for each Semantic Terrain Entity.

In this work, we integrated vector environmental attributes (water currents  $\mathcal{W}$ ) and scalar environmental attributes (depth  $\mathcal{D}$ , water level  $\mathcal{L}$ , environmental modifiers  $\mathcal{M}$ ) into the umbrella "environment"  $\mathcal{E} = (\mathcal{D}, \mathcal{W}, \mathcal{L}, \mathcal{M})$ . Environmental modifiers describe a change of environmental attribute at one point like an abundance of sand, salt, wetness, rocks, etc... As we do not consider the surface geometry in this work, the reader must restrict himself from seeing it as stacks of materials.

### 2.3.2 Semantic Terrain Entity

A geographical feature, also called object or entity, is a discrete phenomenon located at or near the Earth's surface, relevant in geography and geographic information science (GIScience). It represents geographic information that can be depicted in maps, geographic information

systems (GIS), and other forms of geographic discourse. This term includes both natural and human-made objects, ranging from tangible items like buildings or trees to intangible concepts like neighborhoods or savana. Features are distinct entities with defined boundaries, differentiating them from continuous geographic masses or processes occurring over time. They can be categorized as natural features, such as ecosystems, biomes, water bodies, and landforms, or artificial features, such as settlements, administrative regions, and engineered constructs. Geographic features are described by characteristics including identity, existence, classification, relationships with other features, location, attributes, and temporal aspects. Information about these features is stored in geographic databases using models like GIS datasets, which organize and represent these features in structured formats. As the term "feature" is overused in computer science, we will use the term Semantic Terrain Entity in this work.

Each Semantic Terrain Entity has a simple geometric shape called a "skeleton" that defines where it is located and how it fits into the environment. These Semantic Terrain Entities interact with the environment  $\mathcal{E}$  by changing local conditions using the environmental modifier. For example, a river might increase the moisture in the surrounding area, while a mountain might add rockiness. They can also absorb changes from the environment, such as a forest taking in humidity from the air. The placement of Semantic Terrain Entity is determined by a fitness function, which evaluates how suitable a location is based on the environmental attributes. Once a suitable location is found, the skeleton fitting function optimizes the shape and position of the entity to fit as best as possible into the environment.

Semantic Terrain Entities are subject to altitude conditions. However, to maintain a clear distinction between semantic modeling and 3D modeling, we do not compute the exact physical shape or detailed height map of each Semantic Terrain Entity. Instead, we define a coarse height function, a parametric representation derived from the [XXXX] to provide a rough estimate of the changes in elevation around it. This simplified model of how the Semantic Terrain Entity influences the surrounding terrain's altitude allows us to efficiently evaluate the potential presence of new entities that have altitude-dependent conditions without the need to perform expensive computations to generate a detailed height map of the entire terrain.

### 2.3.3 Environmental modifiers

The environment determine if a Semantic Terrain Entity does belong in a position. When a Semantic Terrain Entity is placed, its surrounding environmental attributes can be affected though environmental modifiers. Each Semantic Terrain Entity has intrinsic environmental modifiers that can be seen as "spreading" and "absorbed" around its skeleton over time. A coral reef may produce coral polyps and at the same time reduce the water currents. It grows thanks to the deposition of [RESIDUS CALCAIRES] from coral colonies. In our model, the colonies affect the environmental attributes through the deposition of environmental modifier  $M_{limestone}$ , which in turn, is absorbed by the coral reef, without a direct exchange between the two Semantic Terrain Entities.

The alteration of a scalar environmental attribute is done by adding or removing some amount on the skeleton of the Semantic Terrain Entity and diffusing it in the space, influenced by the water currents. We consider the system to be steady-state, garantied by the introduction of a decay rate  $k$  in the computation of the diffusion.

Altering the vector field of the water currents  $\mathcal{W}$  is done by the addition of the effect of each object at a position  $\mathbf{p}$  as introduced in Wejchert and Haumann, *Animation aerodynamics* (1991), while we use the formulation of Kelvinlets (Goes and James, 2017) in the computation

of effect of each Semantic Terrain Entity.

## 2.4 Placing Semantic Terrain Entities in an environment

At each iteration of our algorithm, we want our objects to be at plausible positions. We do not guaranty a temporal continuity between iterations as in Ecormier-Nocca et al., *Authoring consistent landscapes with flora and fauna* (2021), so the objective is to add new Semantic Terrain Entity in order to satisfy the users wishes, while conserving the plausibility of the scene. For this task, we place a new element required at the most plausible position using the analysis of the fitness function of each Semantic Terrain Entity. We know that each Semantic Terrain Entity will modify the environment surrounding, which may make previously instantiated Semantic Terrain Entities unfitted. Knowing this, the goal is to add the new element at the position that will change the least the stability of the system.

Genetic algorithms or Depth First Search algorithms could be used to try many possibilities until a local or global minimum could be found, but this would require a large processing power. Basic genetic algorithms would place a Semantic Terrain Entity at a certain position at each iteration and evaluate the stability of the environment, repeating this operation while varying slightly the position of the Semantic Terrain Entities or the type of Semantic Terrain Entity instantiated at each iteration, resulting in way too much computation to be interactive. The Depth First Search algorithms requires to compute all the possible combinations of objects and positions which, given the fact that we want a continuous position in order to work multi-scale, would require to compute an incredibly high amount of possible configurations in order to find a plausible situation, on average. We will work with an evolutionary algorithm to find a compromise between fast computation and a satisfying result.

Our placing algorithm is done in two steps: first we estimate at which global location the Semantic Terrain Entity fits the most given an environment using its fitness function, secondly we estimate the shape of the skeleton of this Semantic Terrain Entity should take given a skeleton fitting function.

Generation rules provides, for each Semantic Terrain Entity, a fitness function  $\omega_{STE}$  defining the most probable location for an Semantic Terrain Entity to spawn. Fitness functions' parameters contains, for every point  $p$ , the environmental attributes  $\mathcal{E}_p$  (the amount of each material available  $\mathcal{M}(p)$  and the velocity and direction of the water currents  $\mathcal{W}(p)$ ) and information about surrounding Semantic Terrain Entities  $\mathcal{S}$  (signed distance from the closest punctual Semantic Terrain Entity or curve defining curve- and region-based Semantic Terrain Entities, curvature of the curve, and start and end points of the curve-based Semantic Terrain Entities).

### 2.4.1 Fitness function

Darwinian fitness refers to an organism's ability to survive and reproduce in its environment. It is a measure of how well-suited an organism is to its surroundings, and those with higher fitness are more likely to pass on their genes to the next generation. In a similar vein, the fitness function of a Semantic Terrain Entity evaluates its suitability at a location in the terrain, extending the meaning to living features like forests and non-living elements such as rivers, mountains, or sand dunes.

Whenever a new Semantic Terrain Entity is added to the scene, we desire to position it at the position that would be the most coherent to find it. Rather than "forming" these Semantic Terrain Entities, our method "reveals" them, much like a paleontologist uncovers

fossils during an excavation. A paleontologist does not dig randomly across the Earth to find fossils; instead, they analyze the geological context to identify the most likely locations. Similarly, our method observes the environment and estimates where certain elements are likely to exist. For example, in hydrology, if a river appears to originate from nowhere, it might suggest the presence of a karstic river system upstream. In urban planning, if many roads converge at a certain point, it is reasonable to expect that a city is located there. This approach ensures that Semantic Terrain Entities are revealed in positions that are contextually appropriate and coherent within the landscape.

We will follow the same intuition using a fitness function for each of the Semantic Terrain Entity that may be spawn in the terrain. The fitness function defined  $\omega : \mathcal{E} \mapsto \mathbb{R}$  provides a score providing information on how well the Semantic Terrain Entity may fit in this position. Evaluating this function at multiple position results in an approximation of the fitness map of the entity. Once the most probable position is found, we can find the most plausible shape of the Semantic Terrain Entity using the skeleton fitting function.

Semantic Terrain Entities are evaluated at every iteration in order to determine if they are still fitted to belong at the same position as the previous iteration. For punctual Semantic Terrain Entities, this evaluation is applied at its position  $\omega_{\text{STE}} = f(\mathcal{E}_p)$ . Curve Semantic Terrain Entities are evaluated along the parametric curve  $C$  such that  $\omega_{\text{STE}} = \int_C f(\mathcal{E}_{C(t)}) dt$ . In practice, we compute the evaluation as the average of all control points of the curve  $\frac{1}{n} \sum_i^n f(\mathcal{E}_{C_i})$ . Region Semantic Terrain Entities are evaluated inside their region  $\Omega$  as such  $\omega_{\text{STE}} = \int_{\Omega} f(\mathcal{E}_p) dp$ . In practice, we compute the average of random points in the region  $\frac{1}{n} \sum_i^n f(\mathcal{E}_{p_i})$ . When deformations on the Semantic Terrain Entity's shape is applied, we apply cage deformation using Green's coordinates in order to keep consistent evaluation points during the whole life cycle of an Semantic Terrain Entity.

## 2.4.2 Skeleton fitting function

The seed point of a spawning Semantic Terrain Entity is defined by a stochastic sampling of the plane. We propose different optimization means to find the optimal fitting position, depending on the Semantic Terrain Entity shape.

The spawning position of a punctual Semantic Terrain Entity is found at the local maxima of the fitness function from a seed point. The optimisation process simply follows the field's gradient  $\nabla \omega_{\text{STE}}$  until the local maxima is reached.

A region is defined as an isocontour of the field for which the target area  $A$  is found. From the seed point, we follow the isolevel of the fitness function  $\nabla \omega_{\text{STE}}^{\perp}$  until a loop is created to define the initial condition of the shape. Using the Active Contours algorithm, we can optimize the region's energy defined as  $E = E_{\text{internal}} + E_{\text{shape}}$  with

$$E_{\text{internal}} = \frac{1}{2} \left( \alpha(t) \left\| \frac{dv}{dt}(t) \right\|^2 + \beta(t) \left\| \frac{d^2v}{dt^2}(t) \right\|^2 \right). \quad (2.1)$$

The internal energy  $E_{\text{internal}}$  force the shape compact while the shape energy  $E_{\text{shape}}$  force the shape into a specific target. For the Semantic Terrain Entities generated in the following examples, we used a constraint on a target area.

$$E_{\text{shape}} = (A - a)^2 \quad (2.2)$$

with  $a$  the current area of the shape and  $A$  the target area, provided by the user for each shape, with some randomness.

A curve have different generation rules. It can either follow the gradient of the fitness function  $\nabla\omega_{\text{STE}}$ , follow the isocontour  $\nabla\omega_{\text{STE}}^\perp$ , or follow the heat points. While the first two possibilities are trivial, the later can also be optimized using the Active Contours algorithm by optimizing the energy  $E = E_{\text{internal}} + E_{\text{shape}}$  with Equation Equation (2.1). We applied a length constraint on the curves :

$$E_{\text{shape}} = (L - l)^2$$

with  $l$  the curve's length and  $L$  the target length. This algorithm is sensible to the initial shape of the curve, so we start with a straight line following the isolevel at the seed point.

## 2.5 Environmental attributes and environmental modifiers

The environment is composed of a scalar field for each of the possible material that can be found in the terrain. The scalar fields represents the availability of the material at any point, but not a height field. Each material is defined with a mass  $m$ , a fluid velocity factor  $v$ , a diffusion rate  $D$  and finally a decay rate  $k$ .

Each Semantic Terrain Entity in the terrain is a source and a sink of environmental modifiers. It is the main mean of communication between Semantic Terrain Entities as it allows them to interact with their surrounding environment. We define the amount of deposited material with  $D_M$  and  $A_M$  the amount of material deposited and absorbed by the Semantic Terrain Entity and  $\gamma(t) \in [0, 1]$  a factor related with the current state of the Semantic Terrain Entity, which state that more material will be displaced when the Semantic Terrain Entity is fully formed than when it was just spawn:

$$\int_0^t \gamma(t) (D_M - A_M) dt$$

The deposition and absorption around an Semantic Terrain Entity is defined using the Gaussian kernel distance computation from the skeleton.

The scalar field for the material  $M$  is displaced by using a warp operator  $\Phi$ , taking into account the water flow  $\mathcal{W}$  and the terrain slope  $\nabla\mathcal{H}$ . We unified the warp with  $m$  the mass of the material and  $v$  a influence factor of the fluid on the material:

$$\Phi(\mathbf{p}, t) = m\nabla\mathcal{H}(\mathbf{p}, t) + v\mathcal{W}(\mathbf{p}, t)$$

The environmental modifiers are also dispersed at a diffusion rate  $D$ , for which we can use the advection-diffusion-reaction equation to evaluate the distribution after a time  $t$

$$\frac{\partial M}{\partial t} \Phi \nabla M = D \nabla^2 M - k M \quad (2.3)$$

We solve Equation (2.3) numerically using Euler integration

$$\begin{aligned} M(\mathbf{p}, t + dt) &= M(\mathbf{p}, t) + dt(D \nabla^2 M(\mathbf{p}, t) - k M(\mathbf{p}, t)) \\ &\quad - \Phi(\mathbf{p}, t) \nabla M(\mathbf{p}, t) \end{aligned} \quad (2.4)$$

The introduction of the decay rate  $k$  in the equation allows for the reach of a steady-state, where we can consider the simulation stable. As the user updates the state of the simulation manually, we observe the reach of this steady state before continuing the iterative steps.

The computation of the height  $\mathcal{H}(\mathbf{p})$  is done using the coarse height function of each Semantic Terrain Entity affecting a point  $\mathbf{p}$ . [CONTINUE WITH THE COMPOSITION OF HEIGHTS]

### 2.5.1 Influence on water currents

We define our water currents as a vector field defined as

$$\mathcal{W}(\mathbf{p}) = \mathcal{W}_{\text{user}}(\mathbf{p}) + \mathcal{W}_{\text{simulation}}(\mathbf{p}) + \mathcal{W}_{\text{entities}}(\mathbf{p})$$

With  $\mathcal{W}_{\text{user}}$  a user-defined vector field,  $\mathcal{W}_{\text{simulation}}$  an analytical solution inspired by a wind flow simulation ( Paris et al., 2019a), and  $\mathcal{W}_{\text{entities}}$  the water flow alteration computed from the Semantic Terrain Entities. The component  $\mathcal{W}_{\text{simulation}}$  is terrain-induced. Given an input flow direction  $a$ , we modify the vector field by warping it with the terrain gradient smoothed at multiple scales :

$$\mathcal{W}_{\text{simulation}}(\mathbf{p}) = \sum_{i=0}^{i=n} c_i \Phi_i \cdot v$$

with  $v = (a(1 + k_w \mathcal{D}(\mathbf{p}))$  and  $\mathcal{D}(\mathbf{p})$  the depth at point  $\mathbf{p}$  and  $k_w$  a scaling factor, used to simulate the Venturi effects.  $\Phi_i \cdot v$  is the warping operator at scale  $i$  with a coefficient  $c_i$  defined as

$$\Phi_i \cdot v = (1 - \alpha)v + \alpha k_i \nabla \tilde{h}_i^\perp(\mathbf{p}) \quad \alpha = \|\nabla \tilde{h}_i(\mathbf{p})\|$$

with  $k_i$  a deviation coefficient,  $\alpha$  the slope of the smoothed terrain and  $\nabla \tilde{h}_i^\perp(\mathbf{p})$  the orthogonal vector of the smoothed terrain. As proposed by the authors, we used two scaling levels  $n = 2$  with gaussian kernels of radii 200m and 50m with weights 0.8 and 0.2 and deviation coefficients  $k_0$  and  $k_1$  of 30 and 5.

$\mathcal{W}_{\text{entities}}$  is a deformation field defined as the accumulation of flow primitives ( Wejchert and Haumann, 1991). Kelvinlets are applied on each Semantic Terrain Entities to deflect the water flow. We use the scale and grab formulations of the regularized Kelvinlets brushes ( Goes and James, 2017), denoted as  $s_\varepsilon(r)$  and  $g_\varepsilon(r)$  respectively to simulate obstruction and diversion, are defined as

$$s_\varepsilon(r) = (2b - a) \left( \frac{1}{r_\varepsilon^3} + \frac{1}{2r_\varepsilon^5} \right) (sr)$$

$$g_\varepsilon(r) = \left[ \frac{a - b}{r_\varepsilon} I + \frac{b}{r_\varepsilon^3} rr^t + \frac{ae^2}{2r_\varepsilon^3} \mathbf{I} \right] \mathbf{F}$$

with  $a = \frac{1}{4\pi\mu}$  and  $b = \frac{a}{4(1-v)}$  provided  $\mu$  a shear modulus and  $v$  a Poisson ratio provided for each Kelvinlet,  $r = \mathbf{p} - \mathbf{q}$  for  $\mathbf{p}$  the evaluation position and  $\mathbf{q}$  the center point of the Kelvinlet,  $r_\varepsilon = \sqrt{\|\mathbf{r}\|^2 + \varepsilon^2}$  the regularized distance,  $\varepsilon$  a radial scale for the deformation field,  $s$  a scaling factor and  $\mathbf{F}$  the force vector of the grab operation. Deformations defined on curves use  $\mathbf{q} = C(\mathbf{p})$  with  $C(\mathbf{p})$  the closest point on the curve from the point  $\mathbf{p}$  and  $f = C'(\mathbf{p})$ . We can then define  $u_o(\mathbf{p}) = s_\varepsilon(\mathbf{q} - \mathbf{p}) + g_\varepsilon(\mathbf{p} - \mathbf{q})$ . Finally, we can retrieve the velocity field from the objects:

$$\mathcal{W}_{\text{entities}}(\mathbf{p}) = \sum_{o \in \mathcal{S}} \lambda_o u_o(\mathbf{p})$$

### 2.5.2 Environment stability

Semantic Terrain Entities and environmental modifiers are inspired by the ecological concept of biogeocoenosis, which describes the relationship between living organisms (biotic) and

their non-living environment (abiotic). These interactions closely mirror the processes observed in natural ecosystems, where biotic and abiotic components continuously influence each other, leading to a balanced and stable environment. Gubanov and Degermendzhy [CITATION] describe biogeocoenosis as almost-closed systems, with many parallels possible with thermodynamics such as the concept of dynamic equilibrium. In a biogeocoenosis, the various processes, such as the spread of nutrients, the growth of vegetation, or the erosion of soil, tend toward a state of balance.

Similarly, in our method, the interaction between Semantic Terrain Entities and environmental modifiers is modeled using a reaction-diffusion-advection framework. This model captures how environmental modifiers are spread and absorbed within the terrain. Thanks to the decay rate of the environmental modifiers, the system progresses toward a dynamic equilibrium, where the distribution of environmental modifiers stabilizes. This stabilization reflects a state of balance where the rates of spreading and absorption and decay are equal, and the environmental attributes become coherent across the landscape. For example, a river might spread sediments downstream, which are gradually absorbed by the surrounding terrain, leading to a stable sediment distribution over time. Similarly, moisture emitted by a forest will eventually reach a balance with the surrounding soil and atmosphere, creating a stable, humid environment.

The only factor that can disrupt this equilibrium is a change in the environmental attributes. Changes such as an increase in temperature, a shift in wind patterns, or the introduction of a new Semantic Terrain Entity can alter the balance, leading to a new phase of interaction and stabilization.

## 2.6 User interaction

The user can guide the generation process. The use of simple shapes as Semantic Terrain Entities facilitate the edition of the simulation, as we can interactively add, remove or modify Semantic Terrain Entities, or focus the generation process in a restricted area. Interaction with the environmental attributes is also provided as geomorphic events, that the user can invoke during the simulation. While the direct interactions on the Semantic Terrain Entities are instantaneous, as the geomorphic events are active on a given duration.

### 2.6.1 Direct interactions on the Semantic Terrain Entities

The interactive nature of our simulation enables the user to modify the state of the terrain by manipulating directly the Semantic Terrain Entities of the scene. We assume the modifications applied between two iterations of the simulation.

Translating an Semantic Terrain Entity is trivial, we simply requires to evaluate the state of the Semantic Terrain Entities at a translated position. The deformation of Semantic Terrain Entities can be applied on curve and region Semantic Terrain Entities by updating the control points of the skeleton and recomputing the resulting implicit surfaces. The evaluation positions used for region Semantic Terrain Entities are displaced by applying a cage deformation of the 2D shape using the Green coordinates of points in the shape. After the alteration of the region, evaluation points should be keeping a similar distribution than before, avoiding unexpected results during the interaction. By modifying an Semantic Terrain Entity, the environmental attributes may change, which can result in the destruction of the now incompatible environment objects in the scene (Figure 2.3).

Figure 2.3: Starting from a coral colony developed around a canyon (*left*), the user edits the shape of the canyon, resulting in a different configuration of the scene, killing the corals that ends too deep in the water (*center*) and the development and growth of new corals at the previous location of the canyon (*right*).

As long as a non-zero fitness function is defined in the terrain, new Semantic Terrain Entities can be forced by the user at any point of the simulation.

Control over the region of the terrain that should be updated can be given by adjusting all fitness functions through a scalar field  $\lambda : \mathbb{R}^2 \mapsto \mathbb{R}$  such that the fitness function  $\omega_{\text{STE}}(\mathbf{p})$  of any new Semantic Terrain Entity is evaluated as  $\omega_{\text{STE}}^*(\mathbf{p}) = \lambda \mathbf{p} \omega_{\text{STE}}(\mathbf{p})$ . This is especially useful in the planning of robotic simulations as we can first generate the overall shape of our terrain and secondly focus the generation process around the areas that may be visited by the robot, avoiding useless simulations and computer power. Figure 2.7 shows an example of colonization of the coral polyps that we limited manually into an annulus.

Our water current simulation is modeled as a simple vector field. As such, the user is able to interact with it at any moment of the simulation, allowing for the death of sensible Semantic Terrain Entities while it will guide the simulation into a new landscape. By modifying the water currents, the user also modifies the transport rate of environmental modifiers at this position. The modification of currents is given as a stroke, a parametric curve  $C$  for which we evaluate  $\Delta \mathcal{W}_{\text{user}}(\mathbf{p})$  just as for curved environment objects (Section 2.5.1).

## 2.6.2 Indirect interaction of Semantic Terrain Entities

A configuration file can define in advance the different geomorphic events that should be triggered during the simulation. This can be useful to generate landscapes that are close to some existing locations. Multiple geomorphic events can be triggered either as sudden or continuous environmental changes. These changes play a huge role in the morphology of landscapes. We define geomorphic events with a starting point and an ending point, such that at any time of the simulation we can compute the progress of the geomorphic event as  $t_e \in [0, 1]$ .

Water level changes are important geomorphic events that shape the underwater landscapes. As previously submerged Semantic Terrain Entities get elevated above water level, flora and fauna terrain features dry and die. Deprived from the living part of the features, everything is more affected by terrestrial erosion. By updating the value of the depth  $\mathcal{D}$  evaluated in the fitness functions, any Semantic Terrain Entity that is sensible to the depth will be impacted automatically, that may be causing death (Figure 2.4). The modification of the water level is defined as

$$\mathcal{D}(\mathbf{p}) = \mathcal{D}_0(\mathbf{p}) + \sum_{e \in \text{events}} \Delta \mathcal{D}_e t_e$$

Figure 2.4: Lowering the water level by a few meters caused most of the coral objects to satisfy  $\omega_{STE} \leq 0$ , causing their death. Since the water level (blue) decrease slowly, new coral objects spawn progressively at a lower altitude.

Figure 2.5: Simulating subsidence on a part of the terrain (brown area) cause the depth value to change locally, resulting in the death of coral objects that find themselves too deep to survive. Here two subsidence geomorphic events are triggered in parallel.

with  $\Delta\mathcal{D}_e$  the amount of water rising or lowering during an geomorphic event. We assumed a linear evolution of the water level during an geomorphic event. This allows to evaluate the depth at any point in space and in time.

Subsidence and uplift are the main geomorphic events that create or destroy islands in the long term. These geomorphic events are simulated as a simple factor on the height field of the generated terrain (Figure 2.5). Subsidence is not always uniform in the terrain. As such, the user can provide a position  $\mathbf{q}$  at which the subsidence is the strongest, the amount of subsidence applied  $\Delta\mathcal{H}_e$  and a standard deviation  $\sigma$  for which we can then compute at any point in space and time of the simulation the height of the terrain

$$\mathcal{H}(\mathbf{p}) = \mathcal{H}_0(\mathbf{p}) \cdot \sum_{e \in \text{events}} \frac{G(\|\mathbf{p} - \mathbf{q}\|)}{G(0)} \Delta\mathcal{H}_e t_e$$

with  $G(x)$  the Gaussian function

$$G(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{x^2}{2\sigma^2}\right)$$

Storms are factors of the geomorphology of coral reefs (Oron et al., 2023; Vila-Concejo and Kench, 2016) and coasts (Cowart et al., 2010; Domínguez et al., 2005). Due to the extreme

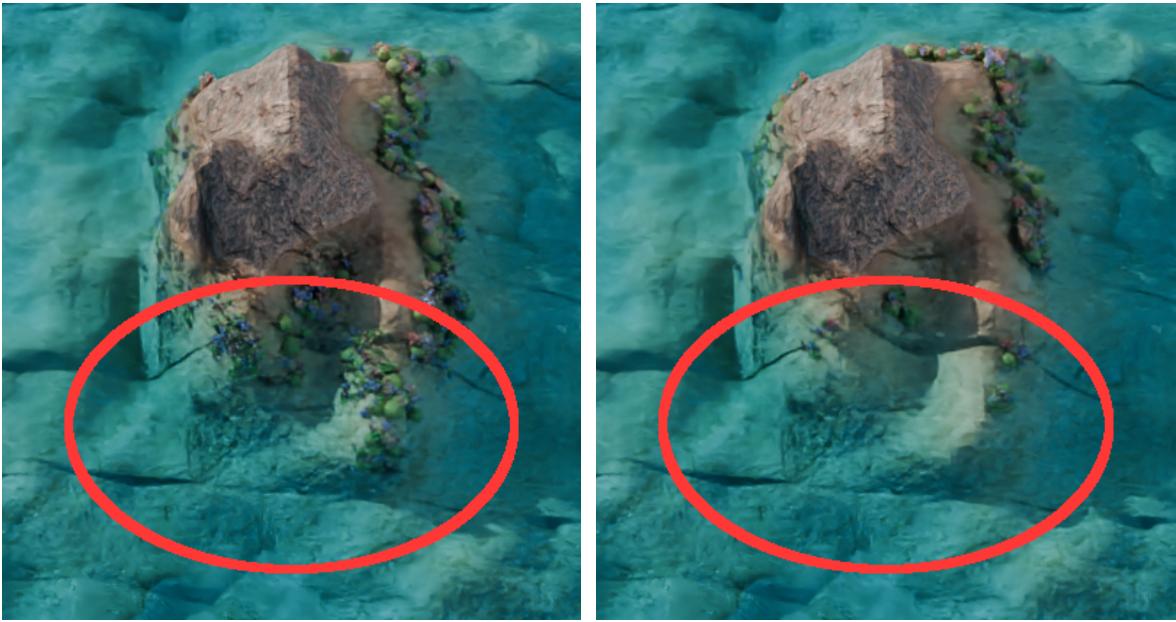

Figure 2.6: The result of a storm localized on one side of the island (red area) modifies the result of the evaluation of Semantic Terrain Entities around its epicenter for a short period of time. Most of the coral objects died from the geomorphic event, except few Semantic Terrain Entities less sensible to water currents strength.

wind and wave velocities coasts are highly eroded in a short time period and the more fragile corals near the water surface are broken, possibly causing breaches in the reefs and spreading polyps in the currents direction. While there are many factors at play to understand the apparition of storms and the hydrodynamics affecting it, we simplified the model of storms to the user as a single epicenter  $\mathbf{q}$  with a wind velocity  $v_{\text{wind}}$  and a standard deviation  $\sigma$  representing the spread around the epicenter (Figure 2.6). The computation of water currents are then computed as

$$\mathcal{W}_{\text{user}}(\mathbf{p}) = \mathcal{W}_{\text{user}}^*(\mathbf{p}) + \sum_{e \in \text{events} | t_e \in [0,1]} v_{\text{wind}} \frac{G(\|\mathbf{p} - \mathbf{q}\|)}{G(0)}$$

In this case, we did not include the linear factor  $t_e$  as storms are usually conserving a constant force for the time of the few weeks or months of their occurrence.

with  $\Delta T_e$  the change of heat during an geomorphic event,  $T_0$  the temperature at the water surface, and  $c$  a very small factor.

The framework can easily be extended as the geomorphic event system stays similar for all geomorphic events. Including higher level simulations in the geomorphic event system can be added, such as the simulation of tectonic activity, the use of fluid dynamics for tsunami geomorphic events, the integration of human activity, ...

## 2.7 Results

Our method provides a way to generate scenes at different scales. We demonstrate this capacity with the generation of a large scene of an island (Figure 2.1) after what we focused the generation process in a canyon (Figure 2.8), then a small-scale visualization of coral colonies (Figure 2.7). In the examples, we rendered the Semantic Terrain Entities as a implicit

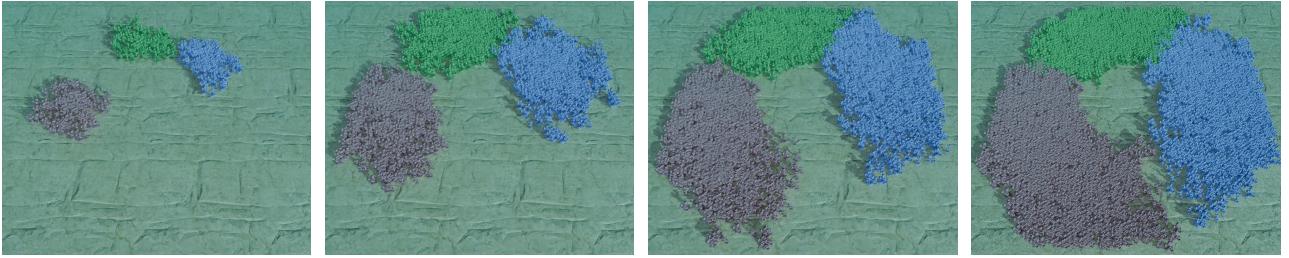

Figure 2.7: Three colonies of coral (red, blue, green) restricted to an annulus the middle section of the terrain fighting for the space.

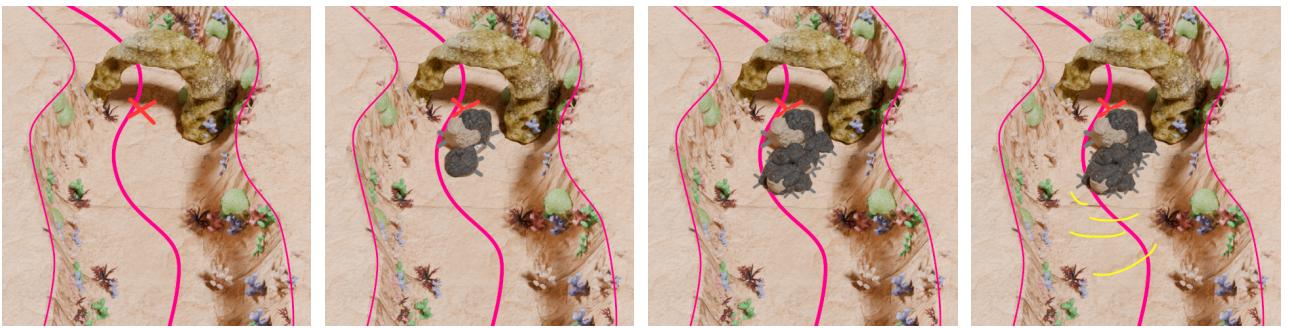

Figure 2.8: Evolution of a canyon scene at different iterations of the simulation. The apparition of an arch causes the spawning of rocks, pebbles, and finally some deposition of sand at the bottom of the canyon, spawning ripples.

tree or as individual meshes. The island, lagoons, reefs, canyons and sand ripples as implicit surfaces

A canyon scene can be generated using our method. The water flow is affected by the curve of the canyon such that the currents are oriented in the direction of the curve's tangent. In this example, we force the position of arches to be inside the canyon. The arches deposits a material "rock deposit", which is the main element of the fitness function of the Rock object. The "rock deposit" is slightly affected by water currents, but its mass make it highly affected by gravity. As such, rocks will spawn underneath arches. In reality, an arch is often created as part of a large coral boulder that sees the calcareous bottom part detached by the water currents, often resulting in an arch surrounded by big rocks and smaller rocks from the erosion of the first rocks. As such, we define an Semantic Terrain Entity "Arch" with a fitness function  $\omega_{arch}(\mathbf{p}) = 5 - d(canyon - \mathbf{p}) * \|\mathcal{W}(\mathbf{p})\|$ , an Semantic Terrain Entity "Rock" using  $\omega_{rock}(\mathbf{p}) = \mathcal{M}_{rock\_deposit}(\mathbf{p})$  and Pebble using  $\omega_{pebble}(\mathbf{p}) = \mathcal{M}_{smaller\_rock\_deposit}(\mathbf{p})$ . Finally, sand ripples are simply described as curves appearing where there is a lot of sand available:  $\omega_{ripple}(\mathbf{p}) = \mathcal{M}_{sand}(\mathbf{p})$ . Following these simple rules, Figure 2.8 shows the emergence of details in the scene.

In this example we defined three different types of corals, coralA, coralB and coralC, to illustrate the possibility to model behaviours from the choice of fitness functions. Each of the coral types deposits a material "coral polyp" and "coral polyp A" ("coral polyp B" and "coral polyp C" respectively). By considering a fitness function that minimize the ratio  $\frac{\text{coral polyp}}{\text{coral polyp A}}$ , we can see an emergent behavior of the three types of coral fighting for the space colonization. Figure 2.7 shows the result of this simulation at three different interations. At the border between two colonies, none of the colonies make progression due to the amount of coral polyp specific from the other colony.

The proposed method aims to generate plausible landscapes using simplified versions

of the evolution of an ecosystem and of the 3D representation. The biological realism of the result is highly correlated to the amount of simplification and assumptions, while the visual realism is completely dependent to the geometric functions used for the 3D modeling of the Semantic Terrain Entities. While proposing a flexible method that propose a generic approach for terrain generation, a close collaboration with fields experts and with graphists is needed to achieve optimal results.

Most simulation algorithm's quality depends on the size of the time step used, but with the introduction of a decay rate in the environmental modifiers properties, we limit the influence of time steps by considering that steady-state are reachable. The material deposition and absorption on punctual Semantic Terrain Entities can be seen as a Dirac function  $\delta$  centered at their position resulting in the advantage that material displacement function can use the definition of the diffusion equation instead of the advection-diffusion-reaction equation. This equation allowing us to evaluate the state of the material  $\mathcal{M}$  without intermediate steps, but this is not applicable with curve- and region-based Semantic Terrain Entities.

## 2.8 Conclusion

We have proposed a method to generate terrains procedurally using sparse representations. This representation, the Semantic Terrain Entities, enables to introduce expert knowledge by the mean of the fitness functions that rule the Semantic Terrain Entities life cycle, but also to integrate the user in the loop during the generation process. We reduced the terrain resolution limitations by defining the environment objects as parametric features. Thanks to the sparse representation based on single points, curves and regions, we allow for direct manipulation of the Semantic Terrain Entities of the scene by the user which, thanks to the environment steady state consideration, also enables to include these interactions in the automatic simulation process. Integrating environmental properties in the fitness function of Semantic Terrain Entities allows the user to guide the generation through geomorphic events. Our method enables each Semantic Terrain Entity of the scene to influence the environment locally, reducing the need of computations while also retrieving environmental attributes locally, which result in a parallelizable life-like simulation process. The genericity of the environment properties definitions should be sufficient for plausible generation of other landscape types as long as expert knowledge can be translated to Semantic Terrain Entity's formalism.

We limited our work to the use of 2D scalar fields as they are more easily differentiable, interpretable and lighter than volumetric representations. However, future works include using 3D representations of the terrain and the environment to generate 3D terrains, including cavities, sub-terrestrial areas and the interior of coral structures.

Figure 2.9: A simple coral island is generated using an island, a lagoon, reefs coral polyps, beaches, trees and algae Semantic Terrain Entities. Trees appear on beaches and algae grow in the lagoon's sand.

## Abstract

---

- Methods completely different
  - \*\* Physical phenomena are different
  - \*\* => Simulation/generation methods must be specific for one landscape
- Methods are developed at different instants of the thesis work,
  - \*\* We will see different procedural generation domains:
    - \*\*\* Analytical solutions (coral islands #1)
    - \*\*\* Deep Neural Networks (coral islands #2)
    - \*\*\* 3D user interaction (karst networks)
  - Deep Learning tends to replace procedural methods in 2D domain,
  - \*\* But still too complex for 3D models
    - \*\*\* (lack of data, lack of research interest for now)
  - \*\* Still requires a lot of data, which, is (while not easy) possible using aerial images, but is way too sparse with underwater landscapes or underground biomes.
  - We want to control the area in which an element is modeled in the terrain
    - \*\* Because that's how we define them in the previous chapter.
    - \*\* Thus we cannot use simple random noise methods => no bounds
      - \*\*\* Only solution is to use falloff maps, but meh...
    - As such, we want to keep the skeleton of our elements using primitives (points, curves, regions)
      - \*\* => Much easier to add constraints / manipulate primitives in a "procedural generation" way.
      - Warning: usage of Deep Learning is at the limit of "procedural generation" and is not considered as part of it by the whole community.

  - \*\* Reevaluation of existing theories

- \*\*\* Critical assessment of long-standing theories with new data
- \*\*\* Adaptation and refinement of theories over time

### Theory 1: Subsidence theory

- Origin and proponents
  - \*\* Charles Darwin (The Structure and Distribution of Coral Reefs, 1842)
  - \*\* Alfred Russel Wallace
- Mechanism
  - \*\* Initial formation around a volcanic island (fringing reef)
  - \*\* Gradual sinking of the volcanic island (subsidence)
  - \*\* Transition to a barrier reef with a lagoon
  - \*\* Complete submersion of the volcanic island leading to atoll formation
- Supporting evidence
  - \*\* Observations from the HMS Beagle voyage
  - \*\* Modern geological surveys and core samples

### Theory 2: Growth on submarine mountains theory

- Origin and proponents
  - \*\* John Murray
  - \*\* Alexander Agassiz
- Mechanism
  - \*\* Coral colonization on underwater mountains (guyots)
  - \*\* Vertical growth of corals towards the sea surface
  - \*\* Formation of atolls without the need for subsidence
- Supporting evidence
  - \*\* Studies on deep-sea coral formations
  - \*\* Distribution of guyots and seamounts in tropical regions

### Theory 3: Sea level change theory

- Origin and proponents
  - \*\* Reginald Daly (The Coral Reef Problem, 1915)
- Mechanism
  - \*\* Impact of glacial and interglacial periods on sea levels
  - \*\* Lowered sea levels exposing coral reefs, allowing vertical growth
  - \*\* Rising sea levels creating conditions for atoll formation
- Supporting evidence
  - \*\* Geological records of sea level changes
  - \*\* Correlation with coral reef growth periods

### Theory 4: Erosion and sedimentation theory

- Origin and proponents
  - \*\* Maurice Ewing
  - \*\* William Donn
- Mechanism
  - \*\* Erosion of coral reefs by waves and currents
  - \*\* Accumulation of coral debris forming islands

- \*\* Continuous process of erosion and sediment deposition
- Supporting evidence
- \*\* Sediment analysis around coral reefs
- \*\* Observations of island formation from coral rubble

### Theory 5: Platform reef theory

- Origin and proponents
- \*\* William Morris Davis
- Mechanism
- \*\* Coral growth on stable continental or insular platforms
- \*\* Formation of reef structures (platform reefs)
- \*\* Development into coral islands when conditions are favorable
- Supporting evidence
- \*\* Studies on platform reefs and their distribution
- \*\* Geological stability analysis of coral platforms

### Comparative analysis

- Similarities and differences
- \*\* Common themes: coral growth, geological activity, sea level changes
- \*\* Differences in primary mechanisms (subsidence vs. growth on seamounts)
- Complementary aspects
- \*\* Integration of multiple theories for a comprehensive understanding
- \*\* Case studies showing multiple processes at work

### Modern advances and technologies

- Geological surveys
- \*\* Core sampling techniques
- \*\* Seismic and sonar mapping
- Environmental studies
- \*\* Impact of climate change on coral growth and sea levels
- \*\* Conservation efforts and their implications for island formation

#### 4.1.2 Darwinian theory

- Several theories
- Difficulty in studying environments
- \*\* Use of observations
- Theory refuted by ( Droxler and Jorry, 2021)
- \*\* But it's too early to judge
- \*\* Practical for our case.
- ...

#### 4.1.3 Overview

- Proposed tool
- \*\* Sketching the island
- \*\* Sketching the profile

- \*\* Wind simulation
- Automation of examples
- \*\* Data augmentation
- ...

## 4.2 Related works

- Perlin + falloff
- \*\* But lacks control
- Uplift [SCHOTT UPLIFT] ( Cordonnier et al., 2016; 2017a)
- \*\* But we propose a method that limits the required interaction
- Sketching [PEYTAVIE SKETCHING, EMILIEN FIRST PERSON] ( Gain et al., 2009)
- \*\* Added radial constraint to simplify interaction
- Geological modeling ( Patel et al., 2021)
- \*\* For us, it's hard to know what's happening underground (?)
- Unlike the literature, integration of the underwater part
- \*\* Integration of observation data into our process
- \*\*\* -> Typical shape and profile of an island
- \*\* Difficult to integrate physical simulations due to uncertainty
- Layer-based generation could improve the realism of examples by considering layer/environment interactions.
- ...

## 4.3 Example generation

- We use Darwin's theory in our case because generation is relatively simple.
- 2 steps:
  - \*\* Generation of the island
  - \*\* Generation of the reef
- Numerous assumptions:
  - \*\* Island has a relatively round shape
  - \*\* Coral grows to a constant height around the island
  - \*\* All "features" are radial
  - \*\* Deformations of islands caused by winds and waves
  - \*\* Islands are independent of each other
  - \*\* The profile is relatively identical all around the island
- ...

### Input

- Sketching of the island from above + profile view
- Wind strength
- Water level
- Subsidence rate
- ...

## "Simulation"

- Subsidence calculated by simple scaling
  - \*\* Note: No geological consistency
  - \*\*\* Here, using a zero level to scale in Z
  - \*\*\* No consideration of different soil materials
- Reef growth
  - \*\* Does not consider any weather events
  - \*\* Considers the "keep up" strategy (as opposed to "give up" and "catch up") [large simplification]
- Wind deformation
  - \*\* using directly  $f(\mathbf{p}) = f(\Phi(\mathbf{p}))$ .
  - ...

## Output

- Height map of the island's surface
- Island zones and coral zones
- Possibility to recalculate ground height and coral height
- ...

### 4.3.1 Closed form of coral growth

- Proposes a closed-form solution for surface calculation
- Calculation of ground height:
  - \*\* Calculation of height by revolution around the origin point
  - \*\* Deformation of the revolution profile using the top-down sketch
  - \*\* Deformation of the height field by the wind map.
- Calculation of growth:
  - \*\* On the initial heightmap,
  - \*\*\* Any surface  $z_{min} < h(p) < z_{max}$  becomes coral
  - \*\*\* Calculation of the "low" contour  $h(p) = z_{min}$  and "high" contour  $h(p) = z_{max}$
  - \*\*\* ...
- Deformation of the map using the wind map:
  - \*\* ...
  - ...

### 4.3.2 Labeling of the map

- Using top-down sketch:
  - \*\* Features "Mountain", "Island borders", "Beach" are radial  $(\theta, r)$ , so we can label each point of the map as the "next" feature
- Using coral simulation information:
  - \*\* Provides the labels "Lagoon" and "Reef {begin, peak, end}".
    - The height map is directly associated to the feature map
  - This is perfect to feed a cGAN.
  - ...

### 4.3.3 Automation

- Take advantage of the radial nature of the features
- Some features can be optional (mountains)
- Deformation of the feature lines
- \*\* Influence on the radius:  $\tilde{r}(\theta) = r(\theta) + \eta(\theta)$  with  $\eta$  continuous noise function  $2\pi$ -periodic.
- ...

## 4.4 cGAN

- Conditional GAN: a type of Generative Adversarial Network (GAN) where the generation process is conditioned on additional information.
- ...

### 4.4.1 Definition of cGAN

- Two networks: consists of two neural networks, a generator and a discriminator, which compete against each other.
- \*\* Generator: takes both random noise and additional information (like class labels or data) to produce synthetic data.
- \*\* Discriminator: evaluates whether a given data instance is real (from the actual dataset) or fake (produced by the generator), while also considering the additional information.
- \*\* Additional information: this can be labels, data from other modalities, or any other contextual information that guides the generation process.
- Training process: the generator tries to create realistic data to fool the discriminator, while the discriminator tries to correctly classify data as real or fake based on both the data and additional information.
- Objective: the goal is to improve the generator's ability to produce realistic data that matches the given conditions and to enhance the discriminator's ability to distinguish between real and fake data.
- Applications: used in various domains including image-to-image translation, text-to-image synthesis, and other tasks where generating data based on specific conditions is required.
- ...

### 4.4.2 Why cGAN?

- Flexibility of input
- Moving beyond the "radial" input condition
- Output even for "inconsistent" data (e.g., ocean in an island)
- No math, geometry, geology, or complicated things to master (hehe)
- ...

### 4.4.3 Training

### 5.1 Introduction

- Definition: complex subterranean systems formed primarily in soluble rocks like limestone, dolomite, and gypsum.
- Importance: significant for water resources, unique ecosystems, and land use management.
- Formation and development
  - \*\* Chemical weathering
    - \*\*\* Study the role of rainwater acidity (carbonic acid) in dissolving carbonate minerals.
  - \*\* Underground drainage
    - \*\*\* Analyze the development of subterranean drainage systems, including caves, tunnels, and sinkholes.
  - \*\* Speleogenesis
    - \*\*\* Examine the process of cave formation, especially at or below the water table.
- Key features of karst networks
  - \*\* Caves and caverns
    - \*\*\* Document major cave systems and their formation processes.
  - \*\* Sinkholes (dolines)
    - \*\*\* Identify areas prone to sinkhole formation and study their causes.

- \*\* Disappearing streams and springs
- \*\*\* Trace the path of streams that vanish into the ground and re-emerge.
- \*\* Karst valleys
- \*\*\* Investigate valleys formed by the collapse of underground voids.
- \*\* Stalactites and stalagmites
- \*\*\* Study the formation of these features within caves.
- Hydrology of karst networks
- \*\* Aquifers
- \*\*\* Assess the productivity and structure of karst aquifers.
- \*\* Groundwater flow
- \*\*\* Model the rapid and turbulent flow of water through karst systems.
- \*\* Vulnerability to contamination
- \*\*\* Evaluate the risks and sources of contamination in karst aquifers.
- Ecology of karst environments
- \*\* Unique habitats
- \*\*\* Research cave-dwelling species (troglobites) and their adaptations.
- \*\* Biodiversity hotspots
- \*\*\* Identify and document biodiversity hotspots in karst regions.
- Human interaction with karst networks
- \*\* Water resources
- \*\*\* Study the dependence of regions on karst aquifers for freshwater.
- \*\* Tourism
- \*\*\* Assess the impact of tourism on karst landscapes and caves.
- \*\* Land use challenges
- \*\*\* Develop guidelines for construction and land use planning in karst regions.
- \*\* Environmental concerns
- \*\*\* Identify and mitigate pollution and land degradation impacts.
- Examples of karst regions
- \*\* The Mammoth Cave System (USA): world's longest cave system.
- \*\* The Guilin Karst (China): unique limestone peaks and river systems.
- \*\* The Dinaric Karst (Balkans): extensive cave systems and karst phenomena.
- Research and study in karst science
- \*\* Speleology
- \*\*\* Promote the scientific study of caves and karst features.
- \*\* Geohydrology
- \*\*\* Conduct studies on water flow in karst systems for resource management.
- \*\* Geomorphology
- \*\*\* Research the development of karst landforms over geological timescales.
- Action steps
- \*\* Field surveys and mapping
- \*\*\* Conduct detailed field surveys and create maps of karst features.
- \*\* Hydrological studies
- \*\*\* Implement hydrological modeling and water quality testing.
- \*\* Ecological research
- \*\*\* Carry out biodiversity assessments and ecological studies in karst habitats.
- \*\* Human impact analysis
- \*\*\* Study the impact of human activities on karst systems and develop mitigation strategies.
- \*\* Education and outreach
- \*\*\* Educate local communities and stakeholders about the importance of karst networks and

sustainable practices.

- Goals

\*\* Conservation

\*\*\* Preserve unique karst ecosystems and landscapes.

\*\* Sustainable development

\*\*\* Ensure that human activities in karst regions are sustainable and minimize environmental impacts.

\*\* Scientific advancement

\*\*\* Promote research and understanding of karst processes and features.

## 5.2 Related works

- State of the art:

\*\* ( Paris et al., 2021)

\*\*\* In our case, we do not rely on a graph and path finder, which allows us to compute sections of the karst on the fly (no need to know the whole network to find paths)

\*\* ( Pytel and Mann, 2015)

\*\*\* Based on voxels, looks plausible, with a low number of parameters, but take way too long (10 to 20 minutes per generation)

\*\*\* Which makes it unfit for user interaction

\*\* ( Collon et al., 2015; 2017)

- With some imagination, we can see the shape of trees:

\*\* [Prusinkiewicz : ANY]

\*\* ( Runions, 2008)

- Or miscellaneous networks:

- Maybe even look for lichen or ant colonies

- ...

## 5.3 Space colonization

- Not really a tree, but...

\*\* Some networks are branching

\*\* Some have low number of cycles

- SC is easy to manipulate for an user

- For these reasons, we will consider the use of SC.

- Description of the algorithm:

\*\* Definition of a root and sinks

\*\* Evolution from the root toward closest sinks

\*\* Branching [WHEN NEEDED]

- ...

## 5.4 Our method

- Based on classic SC

\*\* Merging branches

\*\* Closing paths based on angle and distances to create cycles

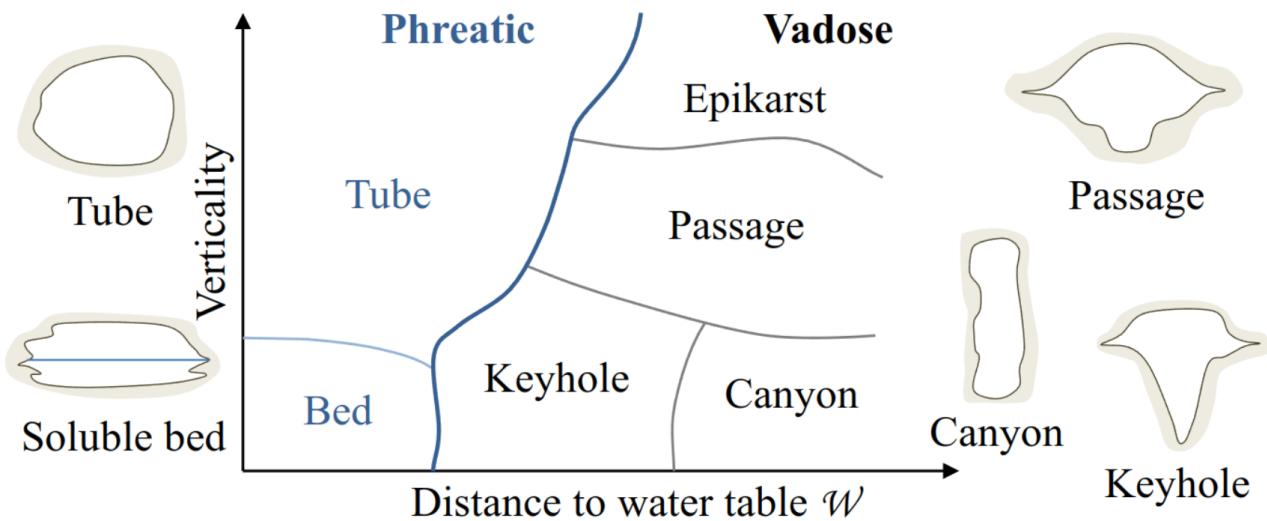

Figure 5.1: Classification of tunnel shapes

- Adding width to the branches
- \*\* Destroying paths when width too small
- Leaves as chambers/cavities
- ...

## 5.5 Modeling

- Tunnels:
- \*\* The output of SC is a set of paths
- \*\* (Paris et al., 2021) provides a classification of tunnel shapes (5.1).
- ...

## 5.6 User control

- Importance of keeping user control
- \*\* Shape of a karst is close to randomness
- \*\* Want to be predictable
- Manipulation of control points
- \*\* Source
- \*\* Sink
- Paths tortuosity
- Inclusion of soil properties in the formation of paths, using the gradient of:
  - \*\* Humidity,
  - \*\* Porosity
- Real-time editing
- \*\* Allows for precise manipulation
- ...

## 6.1 Introduction

Automated terrain generation is a key component of natural scene digital modeling for animated movies and video games. A standard approach is to first generate a base terrain geometry using noise to define the height on the input domain ( Musgrave et al., 1989; Olsen, 2004; Roudier, 1993), the result will most likely lack realism and feel synthetic. Erosion simulation algorithms are applied, to simulate thousands of years of ageing by reproducing physical phenomena - i.e. effects of the elements (rain, wind, running water...) - affecting the terrain making it more believable ( E. Galin et al., 2019; Smelik et al., 2009; Stachniak and Stuerzlinger, 2005).

The process of terrain alteration caused by the effect of water, air, or any other element - natural or not - over time is usually performed in three steps ( Neidhold et al., 2005): **detachment** - pieces of the ground of variable dimensions, ranging from complete ledges to grains of sand, are removed from the terrain depending on the simulated meteorological phenomenon - **transport** - pieces of ground fallen from their initial position are moved to a different one (e.g. a cornice falls down a slope or a grain of sand is thrown into the air) - and **deposition** - transported pieces of land are accumulated at a new part of the landscape. Various phenomena can cause these alterations: **thermal erosion** (bursting of rocks caused by expansion of water under frost, then falling of debris to the bottom of a slope), **hydraulic erosion** (detachment caused by the impact of water particles on surfaces and the transport of sediments by the flow of runoff), **wind erosion** (fine particles carried away in the wind and hit surfaces on their way, creating new fine particles which then also fly away), **chemical erosion** (chemical decomposition of rocks caused by rainwater or other fluids), other exceptional phenomena such as avalanches, animals, lightning, etc... modify the terrain ( Argudo et al., 2020; Cordonnier et al., 2017b; 2017a; 2018; 2023).

In practice, the core idea to simulate erosion is to add or remove material from the terrain at given positions on the interface between the terrain and fluid eroding it (e.g. air or water). Hence, the two major problems to tackle are: how to locally alter the terrain geometry for material detachment and deposition and where to perform these alteration given the properties of the environment (terrain slope, fluid density and velocity). A terrain is more than often represented in 2.5D using a 2D image called a **heightmap** which grey scale values define terrain elevation. While being the major terrain representation, only a limited number of environments can be modeled. Indeed, natural landscapes are intrinsically 3D (overhangs,

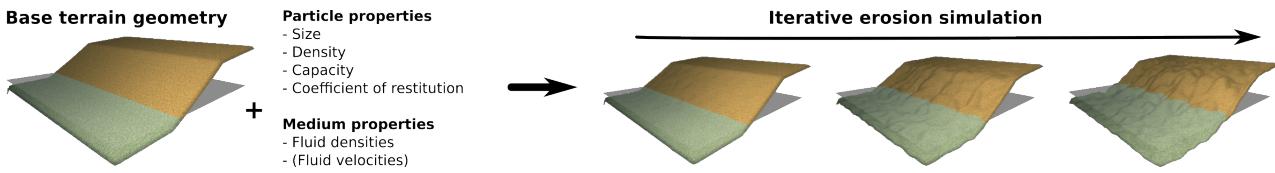

Figure 6.2: Our method require a base geometry, a small number of parameters for the particles and the medium used for the erosion simulation. It can be easily adapted to be compatible with different mediums and terrain representations.

cavities or geological structures such as arches or gobelins), this is particularly true for underwater environments generation. Alternate representation such as voxel grids, material layers or implicit surfaces can be used. A wide variety of method have been proposed to simulate natural erosion phenomena on heightmaps as the partial differential equations to model erosion can be discretized and solved in 2D and the material detachment and deposition at a given point of the terrain surface can be easily performed by elevating or lowering the ground level i.e. changing locally pixel intensities. For volumetric representations, the alteration of the terrain is not as trivial. To define where to perform the erosion process the local slope variations are more than often used combined with eroding medium information. This fluid can be simulated using particle systems, Smoothed Particle Hydrodynamics (SPH) ( Krištof et al., 2009) or approximated using a simple vector field. Proposed methods offer a specific erosion effect tailored to a single terrain representation and fluid simulation.

In this work we propose an approach to simulate a large part of the geomorphological and meteorological phenomena present in the literature of terrain generation (including 3D and volumetric effects). We introduce a generalized algorithm performing the three stages of erosion on surface and volume representations alike, and expose very few intuitive parameters to be adjusted by the user (Figure 6.2). We propose to tackle separately the material variation and the fluid simulation. Our method relies on a particle system to simulate eroding agents, each thrown particle will collide with the terrain, perform terrain alteration at the collision point and transport material along its path. Their motion is computed using simple particle physics accounting for the medium density and particle properties (buoyancy and gravity forces). We consider each particle as independent, hence, they do not interact with each other, no collision detection or response. This simplification allows for efficient parallel computation. When more accuracy or control is needed, we propose to provide a vector field used to modify the particle speed at each time step. The nature of this vector field is flexible, it can be computed using a more or less accurate fluid simulation (SPH, FLIP,...) or be manually defined by the user. We propose a particle-based strategy for material alteration that can be applied on surface and volumetric representation.

The main contributions of this paper are:

- a generalized particle-based algorithm performing the three stages of erosion on surface and volume representations,
- decoupling the erosion system from the fluid simulation, making the process more flexible in its usage and implementation and opening the door for richer effects that can easily be produced.

## 6.2 State of the art

In this section, we first present the major terrain representations (height fields, layered representations, voxel grids, and scalar functions) and a subset of the major simulated phenomena used to erode terrains. We highlight the fact that, in the literature, a specific erosion method tailored to a given terrain representation is proposed for given phenomena which might lead to limitation in term of terrain modeling. Indeed, changing representation costs information and precision loss.

### 6.2.1 Terrain representations

A terrain can be represented in various ways, each of them suited for a given application of which we give an brief overview, more details can be found in ( E. Galin et al., 2019).

#### Height Fields

Height fields represents the surface of the terrain by defining the elevation at each point in a 2D grid. This representation is simple, regular, and fast to process allowing for easy manipulation, such as raising or lowering the terrain ( Emilien et al., 2015; Gain et al., 2009).

#### Layered Representations

Layered representations are an extension of height fields using a 2D grid where each cell represents a stack of different materials instead of a simple height ( Beneš and Forsbach, 2001; Peytavie et al., 2009) allowing for memory efficient representation of volumetric terrains. To create complex structures, arches or caves, solid materials can be transformed into more granular ones, that can be stabilized ( Peytavie et al., 2009).

#### Voxel Grids

Voxel grids are regular, uniform volumetric grids that encode information on the presence or absence of material for each 3D point in the domain. Voxel grids are advantageous due to their regularity ( Dey et al., 2018) and ability to represent volumetric models at the cost of high memory footprint, which has limited their use in terrain generation ( Ito et al., 2003; Kaufman et al., 1993; Lengyel, 2010). We consider two voxel grid representations : *density-voxel* grids for which each voxel contains a scalar value, for instance the occupation percentage ( Eisemann and Decoret, 2008) and *binary voxel* grids that can be seen as a mask containing the presence of material information.

#### Implicit terrains

Implicit terrains represent landscapes as an implicit surface defined by a scalar function. This allows for high definition large terrain modeling. The application of combinable scalar function overlays ( É. Guérin et al., 2016) or the definition of user-defined gradients ( E. Guérin et al., 2022) can be used to create complex terrain features. Altering a implicitly defined surface is a challenging task hence limited option exist for erosion simulation ( Paris et al., 2019b).

## 6.2.2 Erosion processes

Erosion processes play a crucial role in shaping landscapes over time. We present different kind of erosion and how they apply to given terrain representations. Note that using existing methods all erosion methods can not be used on all representation.

### Thermal erosion

Thermal erosion is driven by large temperature shifts, transferring material based on slope thresholds. The process is iterative, redistributing material until slopes stabilize. It can be computed efficiently on height fields and layered terrains due to their manipulable height nature ( Beneš and Forsbach, 2001; Musgrave et al., 1989; Peytavie et al., 2009). However, its application on voxel grids is challenging due to limited Z-axis resolution.

### Hydraulic erosion

Hydraulic erosion stems from water movement, eroding and depositing sediment based on water flow intensity. 2.5D terrains are widely studied for this simulation, using either water slope velocities ( Neidhold et al., 2005) or water simulations for erosion effects ( Mei et al., 2007). For smaller scales, 3D fluid simulations on voxel grids have been proposed ( Beneš et al., 2006). Kristof et al ( Krištof et al., 2009) used SPH (Smoothed Particle Hydrodynamics) for meshless erosion simulations on various terrains. Their method involves numerous particle interactions, demanding significant computational power. Our approach draws inspiration from this but enhances efficiency by removing certain particle interactions.

### Wind erosion

Wind erosion shifts material through wind force, notably impacting areas with fine surface particles like deserts. It has been modeled on discrete height fields ( Paris et al., 2019a; Roa and Benes, 2004) by mimicking sand's wind-driven trajectory and using thermal erosion for corrections. This process is simulated by iteratively displacing small amounts of matter, which make it less suitable for representations with discrete height resolution.

### Erosion by other forces

Erosion comes in many forms. These includes influences like glaciers, snow, tectonic movements, and fauna, each introducing distinctive terrain patterns, enriching its intricacy ( Argudo et al., 2020; Cordonnier et al., 2016; 2017b; 2017a; 2018). However, most methods are tailored by a given terrain representation, often the height fields, and might not be applicable to other representations due to their intrinsic properties.

## 6.3 Particle erosion

Erosion occurs in three stages: material detachment, transport and deposition (respectively in red, black and green in Figure 6.3). In our approach, particles move through the medium following its flow (i.e. wind in air or currents in water) and then absorb or deposit a small amount of material upon contact with the land surface, effectively fulfilling the three stages of erosion.

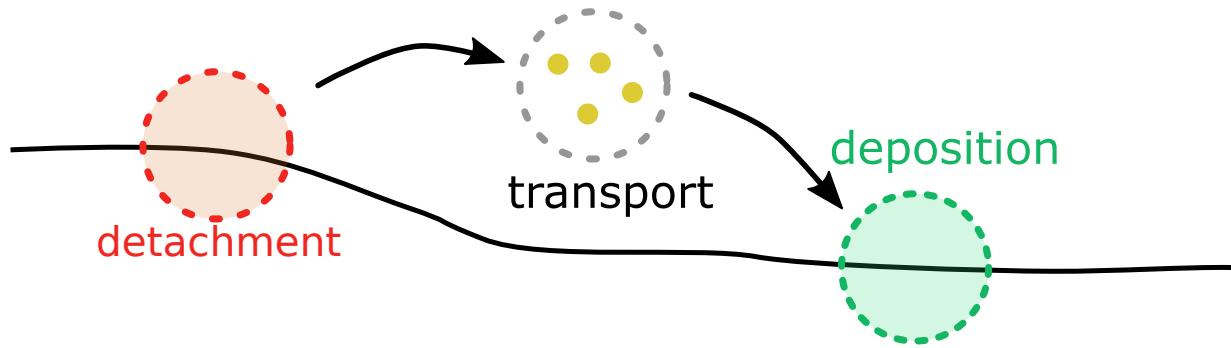

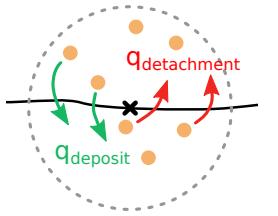

Figure 6.3: Three steps of the erosion process from the sediment point of view: detachment from its original location - dotted red circle -, transport in a fluid - dotted black circle -, deposition at a new location - dotted green circle.

### 6.3.1 Overview

Particles are transported through the medium and can pass through several different media. Each medium is defined by a density and a flow. Consider, for example, water density to be  $1000 \text{ kg m}^{-3}$  and that of air to be  $1 \text{ kg m}^{-3}$ . The gravity applied to the particles is then very different between open and submerged environments due to the difference in buoyancy, while the process remains similar. Using a pre-calculated flow field to guide particle movement simplifies the simulation by treating particles as independent entities, eliminating the need for inter-particle calculations. This not only reduces significantly the overall execution time but also offers users high flexibility over the quality of the simulation and simplify the implementation.

### 6.3.2 Erosion process

Every time the particle hits the ground, a given amount  $q_{\text{detachment}}$  of sediment is detached from the ground (red arrows) while another amount  $q_{\text{deposit}}$  of sediments is deposited at this location (green arrows). Our erosion model is based on the work of Wojtan et al where regular 3D grids are used to estimate the fluid velocity and sediment transport (Wojtan et al., 2007). In the spirit of (Krištof et al., 2009), we transposed their method into a particle-based erosion simulation, but, in our proposition, we decouple the particle system from the fluid simulation, making the process more flexible and opening the door for richer effects that can easily be produced.

#### Detachment

As a particle approaches the surface of the terrain, its motion applies friction at the interface between fluid and ground, causing bedrock to dislocate microscopic parts, that we call abrasion. We use pseudoplastics model to approximate the amount of matter removed due to the shear forces while considering the physical properties of the fluid and the ground (Wojtan et al., 2007).

The shear rate  $\theta$  is approximated by the relative velocity of the fluid to the solid boundary  $v_{\text{rel}}$  over a short distance  $l$ . We approximate the shear stress  $\tau$  at the solid boundary by a power-law:

$$\tau = K\theta^n \quad (6.1)$$

where  $\theta = v_{rel}/l$ ,  $K$  is the shear stress constant (often set to 1) and  $n \in [0, 1]$  is the flow behaviour index. Shear-thinning models typically assume  $n$  close to  $\frac{1}{2}$ , which is why we used this value as a constant.

We can then compute the erosion rate  $\varepsilon$  at any contact point between a fluid and a solid boundary using Equation (6.1) by

$$\varepsilon = K_\varepsilon (\tau - \tau_{\text{critical}})^a \quad (6.2)$$

with  $K_\varepsilon \in [0, 1]$  a user-defined erosion constant,  $\tau_{\text{critical}}$  the critical shear stress value for which the matter starts to behave like a fluid and  $a$  a power-law constant, typically considered as  $a = 1$ .

In our method, the eroded quantity is approximated as the material contained in the half sphere, of radius  $R$ , in the normal opposite direction at the particle impact point (Figure 6.6). We then use Equation (6.2):

$$q_{\text{detachment}} = \varepsilon \frac{2\pi R^3}{3} \quad (6.3)$$

to get the final eroded amount  $q_{\text{detachment}}$ . The particle is also defined by a maximal amount of sediments that can be contained in its volume before being saturated noted  $C_{\max}$ . Note that this constant will be used for the settling velocity computation Equation (6.7).

## Deposition

The eroded sediments are considered in suspension in a fluid and are affected by its velocity. A fluid particle then transports the sediments in its flow until gravity settles it onto the ground again. The effect of gravity is modeled by a settling velocity  $w_s$  defined in Eq Equation (6.7). We consider that the amount of sediment settled is proportional to the norm of the settling velocity as proposed in (Wojtan et al., 2007) with  $\omega \in [0, 1]$ :

$$q_{\text{deposit}} = \omega \|w_s\|. \quad (6.4)$$

### 6.3.3 Transport

Our simulation is computed by integrating the full trajectory of multiple particles at each iteration unlike most other erosion methods. This allows to constantly have a terrain in a plausible state, while giving the possibility to increase the aging effect by running more iterations. Note that, reducing progressively the overall erosion strength can be used as a strategy to adapt the computation time to a chosen level-of-details.

We first present how to compute the particle speed using particle's physics then how to add optional medium velocity field to add a fluid simulation or user control.

## Particle's physics

From its independence with other particles: we consider each particle following Newton's laws of motion.

First, we define the external forces  $\vec{F}_{\text{ext}}$  applied on each particle, we consider gravity and buoyancy. We calculate the buoyancy force  $\vec{F}_{\text{buoyancy}} = -\rho_{\text{fluid}} V \vec{g}$  with  $\rho_{\text{fluid}}$  the density of the fluid,  $V$  the volume of the particle and  $\vec{g}$  the gravitational acceleration, but we can also calculate the force of gravity  $\vec{F}_{\text{gravity}} = m_{\text{particle}} \vec{g}$  with  $m_{\text{particle}}$  the mass of the particle. We

Figure 6.4: The coefficient of restitution affects the amount of energy absorbed from the particle when hitting the ground. Here, rain is applied on an initial slope (yellow). Only two particles are displayed, with a high (blue) and low (red) coefficient of restitution. The resulting slope after erosion is displayed in blue and red (right).

then have the final external force  $\vec{F}_{\text{ext}} = \vec{F}_{\text{gravity}} + \vec{F}_{\text{buoyancy}} = m_{\text{particle}}\vec{g} - v_{\text{fluid}}V\vec{g}$  knowing the density of an object  $\rho_{\text{particle}} = \frac{m_{\text{particle}}}{V}$ , we have:

$$\vec{F}_{\text{ext}} = V\vec{g}(\rho_{\text{particle}} - \rho_{\text{fluid}}). \quad (6.5)$$

The particle velocity  $v$  can be integrated from Equation (6.5) by:

$$v = \int \vec{F}_{\text{ext}} dt + w_s + v_0, \quad (6.6)$$

with  $w_s$  the settling speed of sediments in a fluid with a viscosity  $\mu$  given by Stoke's Law ( Stokes, 2009):

$$w_s = \frac{2}{9}\vec{g}R^2 \frac{(\rho_{\text{particle}} - \rho_{\text{fluid}})}{\mu} f(C). \quad (6.7)$$

We use the Richardson-Zaki relation as the hindered settling coefficient:

$$f(C) = 1 - \left( \frac{C}{C_{\max}} \right)^n$$

with  $C$  and  $C_{\max}$  respectively the fraction of volume of sediments contained and the maximal fraction of sediments the particle can contain, and  $n$  an exponent typically 4–5.5, which we set to 5 ( Richardson and Zaki, 1954; Wojtan et al., 2007).

Finally, the particle position can be integrated as:

$$\mathbf{p} = \int v dt + \mathbf{p}_0.$$

When the particle hits the ground, a coefficient of restitution affects its behaviour by reducing its velocity post-collision. This value depends on ground material as it is influenced mainly by the material's particle shape, coefficient of friction and density ( Yan et al., 2020). Less bouncy particles lose speed quickly and settle down sooner, forming a steeper pile (Figure 6.4 blue), or a higher talus angle like chalk. On the other hand, more bouncy particles disperse more widely upon hitting a surface, resulting in a gentler accumulation like clay (Figure 6.4 red).

## Velocity field

In our model, we allow the user to add a velocity field to the environment that influences particles motion. This velocity field can be the result of a complex fluid simulation, a uniform

vector field, or an artistic motion field. We modify Equation (6.6) such that the particle's speed will be influenced by the velocity field as follows:

$$v = \int \vec{F}_{\text{ext}} dt + w_s + \alpha v_{\text{fluid}} + v_0, \quad (6.8)$$

with  $v_{\text{fluid}}$  medium velocity field modulated by  $\alpha \in [0, 1]$ .

Our particle system can model intricate scenarios, like the erosion caused by water currents on the seabed or aeolian erosion. The velocity field remains static during the erosion, which may cause inconsistencies in the fluid velocity field. However, minor changes can be overlooked to maintain a balance between realism and computational efficiency (Tychonievich and Jones, 2010). We offer several velocity improvement methods:

- **Fluid simulation refinement:**

Many erosion systems incorporate fluid simulation, requiring regular updates for erosion and velocity (Krištof et al., 2009; Wojtan et al., 2007). Our method can use fluid simulations with multi-resolution refinement, with the possibility to focus the velocity field adjustments near the updated boundaries of the surface (Roose et al., 2011).

- **Particle velocities in fluid simulation:**

With a Lagrangian fluid simulation relying on particle systems (Koschier et al., 2022), our particle velocities can be incorporated in its computation. This approach is only a provisional solution due to potential parameter mismatches with main fluid simulation.

- **Velocity field diffusion:**

Given the minor changes to the surface level at each erosion iteration, which reflect the gradual alterations in terrain surface, we can estimate that the velocity at a fixed point transitioning between the inside and outside of the terrain closely mirrors the velocities observed in its surrounding area. In this context, we can simply interpolate the velocity field at any transitioning point. This simple method, as used in Figure 6.8, allows us to find a balance between achieving realistic flow simulations and maintaining computational efficiency.

## 6.4 Our erosion method

In this section, we describe how to apply detachment and deposition to different terrain representations with our method (Figure 6.5). We cover the most commonly used representations namely height fields, layered terrains, voxel grid and implicit surfaces, note that our work could be extended to additional representations. Two conditions need to be satisfied for a representation to be eligible for our erosion method: being able to evaluate the intersection of a particle with the ground and compute the normal of the terrain at this point. To the best of our knowledge, all representation do.

We use Verlet integration for the particle's physics (Verlet, 1967), with low error rate and stability even for high  $dt$ , reducing computation time for negligible imprecision (Baraff and Witkin, 1998; Swope et al., 1982).

For all the representations, the amount of material absorbed by the particle, i.e. the erosion value  $q_{\text{detachment}}$  from Equation (6.3), is taken around the particle at a radius  $R$ , meaning that the modification of the terrain by a particle at position  $c$  will only occur for the positions

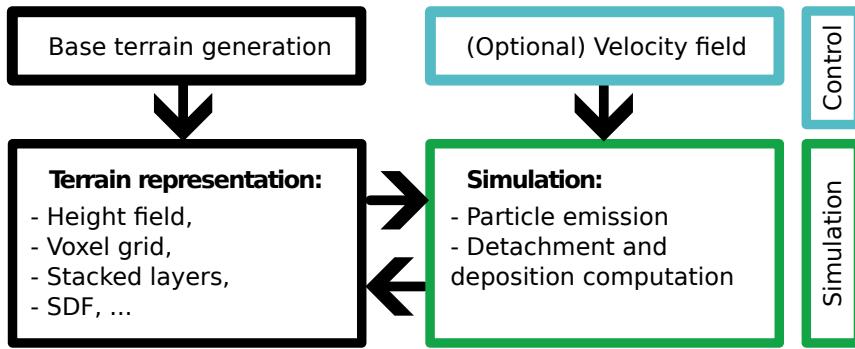

Figure 6.5: Our overall pipeline: our erosion process compute matter displacement of a terrain using an arbitrary representation as long as intersections between particles and the ground can be detected. An optional velocity field, provided by the user, guides the particles trajectories. We propose surface alteration methods to apply the erosion to the terrain in a coherent way between possible representations.

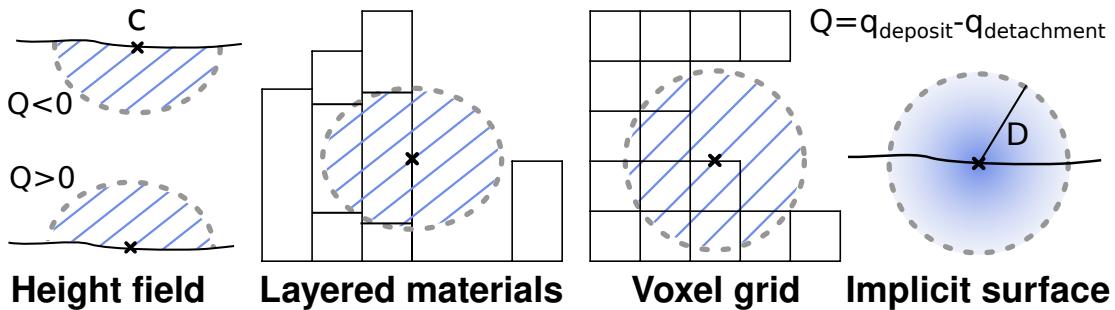

Figure 6.6: Illustration of the material detachment in the (half-)sphere at contact point C (cross) on different representations. (height field) When  $Q < 0$  material detachment happen in the bottom scaled half sphere of the particle's contact with the ground, while the deposition is applied on the upper half sphere of volume when  $Q > 0$ . Unlike the height field, for 3D terrains detachment and deposit are applied in the full sphere around the contact point.

$\mathbf{p}$  satisfying  $\|\mathbf{p} - \mathbf{c}\| < R$ . At the same time, the amount  $q_{\text{deposit}}$  from Equation (6.4) is deposited, resulting in a change  $Q = q_{\text{deposit}} - q_{\text{detachment}}$

In our simulation, while the dynamics are informed by physical principles, the particle size is conceptualized within a dimensionless framework. This provides the flexibility to adapt our results to various real-world scales, ensuring the applicability of our model across diverse scenarios. Note that, for a 2.5D terrain, we can consider that half of the sphere surrounding the particle is affected which has a volume of  $V_{2.5D} = \frac{2\pi R^3}{3}$  while a 3D terrain is affected by the full sphere  $V_{3D} = \frac{4\pi R^3}{3}$  (as illustrated Figure 6.6). In the following sections, we will describe the strategies used to modify the amount of matter for different representations.

#### 6.4.1 Application on height fields

On a height field defined by  $h(\mathbf{p}) = z$ , the intersection point with the surface is verified at  $\mathbf{p}_z = h(\mathbf{p})$ , and the normal can be computed at the intersection point.

For this representation, the half sphere is scaled in the  $z$  direction to fit  $\alpha V = Q$  using  $\alpha = \frac{Q}{V}$ . We then can decrease the height  $h'(\mathbf{p})$  at all points  $\mathbf{p}$  by the height of the scaled half sphere at position  $\mathbf{p}$ . Given the height of the scaled half sphere of center  $\mathbf{c}$  and the distance of the particle to the center  $d = \|\mathbf{p} - \mathbf{c}\|$  by  $h_{\text{half sphere}}(\mathbf{p}) = \alpha \sqrt{R^2 - d^2}$  for all  $\mathbf{p}$  such that  $d \leq R$

the radius around a particle.

This change of height can be sampled at all points of the 2D grid by reducing the height by

$$\Delta h(\mathbf{p}) = \frac{\sqrt{R^2 - d^2}}{\alpha} = \frac{Q}{\frac{2}{3}\pi R^3} \sqrt{R^2 - d^2} \quad (6.9)$$

The height at each point after an erosion is then computed as  $\tilde{h}(\mathbf{p}) = h(\mathbf{p}) + \Delta h(\mathbf{p})$ .

### 6.4.2 Application on layered terrains

Layered terrains are defined as  $\mu : \mathbb{R}^3 \mapsto \mathbb{N}$  assigning a discrete material index  $\mu$  for any point in space ( Beneš and Forsbach, 2001; Peytavie et al., 2009). In the original work, outer borders stack elements of the terrain are transformed into density-voxels to enable global erosion through height changes. We enable the erosion/deposition process directly on the layers hence removing the need for representation changes.

When intersecting the terrain, the amount eroded for each material stack should be the integration of the volume of the intersection between the sphere surrounding the particle and the cubicle represented by the stack. Since there is no easy solution ( Jones and Williams, 2017), we approximate the volume of the stack we need to alter using the previously defined height field equation Equation (6.9). At a distance  $d$  from the particle, the height is defined as:

$$H(d) = \frac{|Q|}{\frac{2}{3}\pi R^3} \sqrt{R^2 - d^2}. \quad (6.10)$$

If  $Q > 0$  (more deposition is applied than detachment) then we transform the materials in the stack contained in the sphere to become ground material. For  $Q < 0$  the materials are transformed in background material.

### 6.4.3 Application on implicit terrains

Implicit terrain are defined using a function  $f(\mathbf{p})$  and its variation resulting from the erosion process using  $\Delta f(\mathbf{p})$ . We propose a strategy to compute  $\Delta f(\mathbf{p})$  at any point of the sphere surrounding the erosion point based on metaball primitives. At each contact point a metaball is added to create a hole or a bump in the terrain. A metaball is defined as:

$$\Delta f(\mathbf{p}) = \frac{3Q}{\pi} \frac{(1 - d)}{R} \quad (6.11)$$

with  $d$  the distance of the point  $\mathbf{p}$  to the sphere center. For all point  $\mathbf{p}$  for which  $d \geq R$ ,  $\Delta f(\mathbf{p}) = 0$  (see .3).

As they are the most commonly used representations, we propose a formulation to erode implicit terrains defined by Signed Distance Functions (SDF) and by gradient or vector fields.

#### Signed Distance Functions

Considering SDF, the terrain is defined as the 0-set of the signed distance function  $f : \mathbb{R}^3 \mapsto \mathbb{R}$ , hence, for  $f(\mathbf{p}) = 0$ , the inside as  $f(\mathbf{p}) < 0$  and outer-part (i.e. air or water) as  $f(\mathbf{p}) > 0$ .

The particle erosion applies at impact points at discrete positions, so we propose to add or subtract metaballs defined using equation Equation (6.11) to respectively deposit or erode

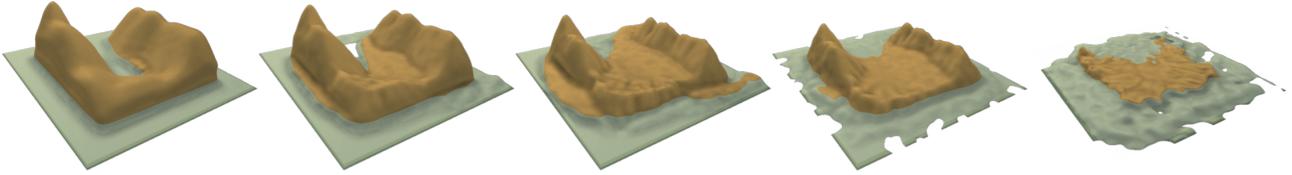

Figure 6.7: Our erosion method is applied iteratively on a completely synthetic island, the terrain is altered to obtain a plausible shape by forming rills. The use of particles with hydraulic densities dropped from the sky results in a strong erosion on the sides of the mountains, and the particles that slide to the sea are mainly drifting offshore resulting in the formation of small beaches and a weaker erosion on the bottom of the water body. Repeating the process causes the island height to decrease progressively up to the point where only the submerged part of the terrain is sheltered from erosion.

material using a composition tree:

$$\text{metaball}(\mathbf{p}) = -\Delta f(\mathbf{p}).$$

Now the eroded terrain function  $\tilde{f}(\mathbf{p})$  will be evaluated at each point  $\mathbf{p}$  from the initial terrain value  $f(\mathbf{p})$ , the erosion function  $\text{metaball}(\mathbf{p})$  and the composition function  $g(f_1, f_2)$ :

$$\tilde{f}(\mathbf{p}) = g(f(\mathbf{p}), \text{metaball}(\mathbf{p})).$$

As a metaball is added for each particle bounce on the terrain space partitioning optimization algorithms such as k-d trees, BSP trees or BVH can easily be used to improve performances.

### Other implicit terrains

are present in the literature, notably a 2.5D representation based on the surface gradient ( E. Guérin et al., 2022) and a 3D representation based on curves ( Becher et al., 2017) for which the trajectory of each particle projected to the closest surface could be used to define the alteration of the terrain.

In the case of gradient-based representation, we propose to use the partial derivative from the equation of the 2D scalar fields Equation (6.9) that gives:

$$\nabla h' = -\frac{Q}{\frac{2}{3}R^3} \frac{1}{\sqrt{R^2 - d^2}} \vec{CP} \quad (6.12)$$

with  $\vec{CP}$  the vector from the position  $\mathbf{p}$  to evaluate to the center of the erosion point  $c$ . Now the new gradient field can be computed as:

$$\nabla \tilde{h}(\mathbf{p}) = \nabla h(\mathbf{p}) + \nabla h'(\mathbf{p}).$$

### 6.4.4 Application on voxel grids

We consider two of the voxel grids representations: density-voxel grids and binary voxel grids for which we present our material alternation strategy.

## Density voxels

We consider "density-voxel" grids defined on  $f : \mathbb{Z}^3 \mapsto [-1, 1]$  for which a voxel is full for  $f(\mathbf{p}) = 1$ , partially full for  $-1 < f(\mathbf{p}) < 1$  or empty for  $f(\mathbf{p}) \leq -1$ . This definition allows us to erode them smoothly. Since this kind of grid is a discretization of a scalar function, We could directly use Equation (6.11), as described previously, but we take advantage of the discrete nature of the representation to avoid expensive computation.

We apply the erosion from a particle at position  $c$  on all points  $\mathbf{p}$  in the volume proportionally to the distance from the center of the sphere  $d = ||\mathbf{p} - c||$  to find an approximation to the real erosion value per voxel  $Q_{approx} = Q \frac{1-d}{R}$ . Using their discrete nature, we rectify this value to sum up the total erosion value to  $Q$  by dividing each value by the sum of the distances. We now consider eroding the "empty" voxels since their density can drop until  $-1$ . We then have for all surrounding voxels:

$$\Delta f(\mathbf{p}) = Q \frac{(1 - \frac{d}{R})}{\sum (1 - \frac{d}{R})}. \quad (6.13)$$

Resulting voxel value is computed as  $\tilde{f}(\mathbf{p}) = f(\mathbf{p}) + \Delta f(\mathbf{p})$ . In our implementation, when  $f(\mathbf{p}) > 1$ , we simply transport the density excess to the above voxel, giving it a very close analogy to height fields as long as  $|\Delta f| < 1$ .

## Binary voxels

The terrain can be represented using an occupancy function as  $f : \mathbb{Z}^3 \mapsto \{0, 1\}$  where a voxel  $f = 1$  defines the ground and  $f = 0$  the background.

We propose to apply particle erosion by assigning voxels a number of hits, and transform them as air or as ground when this number reaches a critical value  $C$  that is proportional to the particle's strength parameter  $K_e$  ( Beardall et al., 2010).

On a hit, all voxels in a radius  $R$  receive a hit number:

$$\Delta hits = \lfloor \alpha \Delta f \rfloor \quad (6.14)$$

with  $\Delta f$  the erosion per voxel computed using Equation (6.13) and  $\alpha$  a coefficient high enough to obtain values above 1.

All voxels with  $\#hits > C$  are transformed to background and voxels with  $\#hits < -C$  are transformed to ground.

Note that, a binary voxel grid can also be transformed into a density-voxel grid to be eroded smoothly.

Our formulation for height fields Equation (6.9), can be used to erode 2D scalar field-based representations. Similarly, our proposition for SDF Equation (6.11) enables erosion for continuous 3D scalar fields and voxels Equation (6.13) for discrete 3D scalar fields respectively.

## 6.5 Results

Our erosion process enables the simulation of a wide range of erosion effects on the major terrain representations alike. In this section, we present applications that demonstrate the versatility of our method by changing the particle's effect size, quantity, density, maximum capacity, deposition factor and the velocity fields. The results of each process are presented in Figure 6.14, parameters used are available at Table 6.1. It is important to note that all erosion

Table 6.1: Parameters used for the generation of the terrains presented in Figure 6.14, with "Rep" the representation (H: Heightmap, DV: Density-voxels, BV: Binary voxels, I: Implicit) "Res" the resolution in meter per voxel or cell, #P the number of particles per iteration, #N the number of iterations, R the particles radius (in voxel or cell unit), COR the coefficient of restitution,  $\rho_{\text{particle}}$  the particle density in  $\text{kg m}^{-3}$ ,  $C_{\text{factor}}$ ,  $\varepsilon$  and  $\omega$  respectively the capacity, erosion and deposition factors, "Vel field" the type of velocity field used and t the computation time of the simulation in seconds on CPU.

(<sup>1</sup>) The velocity field is a vector field defined as  $v_{\text{fluid}}(\mathbf{p}) = [0 \sin(\mathbf{p}_x) 0]^T$ .

examples presented in this section are available for any 3D terrain representation. However, we cannot create volumetric structure, such as overhangs, using 2.5D representations (height fields).

Environment density  $\rho_{\text{fluid}}$  is set to  $1 \text{ kg m}^{-3}$  above water level (terrain blue part) and to  $1000 \text{ kg m}^{-3}$  below it. Velocity field's refinement is done by using the presented diffusion strategy.

### 6.5.1 Rain

Hydraulic erosion from rain is the most common process used in terrain generation. In this case, particles are seen as water droplets falling from the sky and rolling downhill due to the gravitational force of Earth. No velocity field is required from fluid simulation. These parameters result in a detailed geometry of the rills on the side of mountains that quickly emerge and deposit many sediments in the valley. We demonstrate the result of rain erosion in *Figure 6.14: Rain* with a computation time of 4 seconds.

Using this erosion parameters in combination with water bodies results in different outcomes (Figure 6.7). The terrain above water is directly affected by the erosion process while particles colliding with the underwater part of the terrain are slowed down and filled with sediments, leading to mainly apply deposition. The result is a typical hydraulic erosion on mountains and the formation of slopes and beaches near water level.

### 6.5.2 Coastal erosion

Waves repeated motion creates coastal erosion, that can be seen as cliffs with holes at the water level.

We apply a uniform velocity field in the water pointing towards the coast to simulate waves and emit particles from the water area with a large size, a density between air and water densities, a high capacity factor and a low deposition factor  $\omega$ . Using these parameters, the

erosion process is focused at the interface of air and water, and apply a coarse detachment while depositing a very small quantity of sediments, simulating the corrosive effect of water on limestone.

This effect can only be simulated on 3D terrain representations, but will create cliffs on a 2D representation. *Figure 6.14: Coastal* presents the result of coastal erosion on a density-voxel grid that creates overhangs around sea level using a small amount of particles. Note that, the same effect using an alternate implicit representation based on SDF is displayed in Figure 6.10. A shaded version of this effect is presented in Figure 6.1.

### 6.5.3 Rivers

Given a source point, we generate particles that run downhill, simulating the formation of a river. More complex erosion simulation using fluid simulations like SPH ( Krištof et al., 2009) would create realistic results at the cost of high processing time. Our method offers the flexibility to be applied either with a velocity field (simple, used given or resulting from a fluid simulation) or without allowing for simplicity and efficiency.

When provided with a hand-made or procedural velocity field, our particle system can reproduce simple river meanders (*Figure 6.14: Meanders*).

*Figure 6.14: River* presents a river that has been modeled by emitting water particles with different sizes that ranges from 1.5 m to 5 m, a high coefficient of restitution and a low capacity factor. Random sizes are used to simulate a river for which the flow rate had fluctuated over formation time, while the low capacity ensure that the banks of the river stays smooth. A high coefficient of restitution is a strategy that let the particles flow with low friction, approaching a water behaviour. Our particles are affected only by gravity, without fluid simulation.

### 6.5.4 Landslide

are mainly caused by large amount of water saturating the ground and flowing downhill, transporting matter in its path.

By using water particles with a medium size, a low coefficient of restitution and a low capacity factor but a high deposition factor  $\omega$ , they transport sediments on short distances as the velocity quickly drops to 0, and ground material is completely spread along its path since it is easier to deposit the same amount of sediment than the eroded amount at each collision point. Reducing the density of the particle simulates a rise of viscosity in the settling velocity formula, increasing again the quantity of matter to deposit at contact with the ground. By this means, we can simulate landslides as illustrated on *Figure 6.14: Landslide*. A smoother surface is resulting, compared to the rain erosion as the rills are filled with sediments as soon as they begin to form. By setting the initial capacity of the particle equal to 10% of its max capacity, the mass of the terrain increases, simulating a volcano eruption as illustrated on *Figure 6.14: Volcano*.

### 6.5.5 Karsts

networks are created over hundreds of years from the corrosion of water on the limestone in the ground. A limited number of methods have been proposed for the procedural generation of karsts ( Paris et al., 2021).

By reducing the deposition factor  $\omega$ , the particles simulate corrosion (without mass conservation). We can use the same particle parameters than the coastal erosion (big size, a density between air and water densities, a high capacity factor and a low  $\omega$ ) and optionally provide

a 3D shear stress map. The karst will automatically follow the softest materials, which is geologically coherent as given in example in *Figure 6.14: Karst*, where we can observe a "pillar" that is formed in the center, and thus the karst forms two corridors that finally merge partially. Underground results are only available for representations allowing 3D structures. Another underground terrain simulation is shown in *Figure 6.14: Tunnel* in which a water runoff is eroding a tunnel without the use of a fluid simulation. Here, when particles bounce often on the terrain surface, the coefficient of restitution may be seen as a viscosity parameter.

### 6.5.6 Wind

erosion is a significant process in desertscape shaping since there are no obstacles on the airflow path. Air particles can reach high velocities, transporting sand over long distances forming either dunes or are blasted into rocks, eroding into goblins.

By setting the density of our particles close to  $1 \text{ kg m}^{-3}$ , two erosion simulations can be applied at once. Air particles follow closely the flowfield given by the user in air. This flowfield can be given from a complex simulation, a user-defined wind rose ( Paris et al., 2019a) or a random flowfield with a general direction.

The generation of the different sand structures depends on the velocity field provided, and a simple field will easily generate linear dunes. On contact with a rock block, the simulation will automatically erode block borders, creating shapes looking like gobelins.

*Figure 6.14: Wind* gives an example of wind erosion on a flat surface with rock columns being eroded. Given a strong 2D velocity field computed by the high wind simulation proposed in ( Paris et al., 2019a) is used on light particles, the simulation is fast thanks to the low number of collisions each particle has with the ground.

### 6.5.7 Underwater currents

Procedural generation of underwater 3D terrains has received little attention. The difference between the underwater and the surface rely on the buoyancy force that is much stronger, meaning that the water flow has a much more impacting effect on erosion than wind. Taking into account the density of the environment and the velocity field of water in our formulas are the keys to be able to apply any erosion in this environment. Our method works in a water environment by giving at least water density to particles. Given a velocity field describing underwater currents from a complex simulation or from a sketch, the particle system erodes the terrain.

In the example presented in *Figure 6.14: Underwater*, the velocity field is given by a simple 3D fluid simulation ( Stam, 1999) applied on the terrain.

A complex water flow simulation is computed using SIMPLE ( Caretto et al., 1973) fluid simulation with OpenFOAM. The resulting erosion can then follow complex water movement and erode the terrain at the most affected parts of the 3D terrain as the trajectories of the particles (green) is highly affected by the fluid velocity (blue). The density of the particles and the environment being close, the buoyancy cancels most of the gravity force, leaving the velocity of the particles computed by the fluid velocity  $v_{\text{fluid}}$  and settling velocity  $w_s$  from Equation (6.8) (Figure 6.8).

### 6.5.8 Multiple phenomena

A terrain eroded with multiple erosion phenomena applied on a 500x500x50 density-voxel grid is illustrated in Figure 6.9. Here, water-density particles are applying rain on the terrain

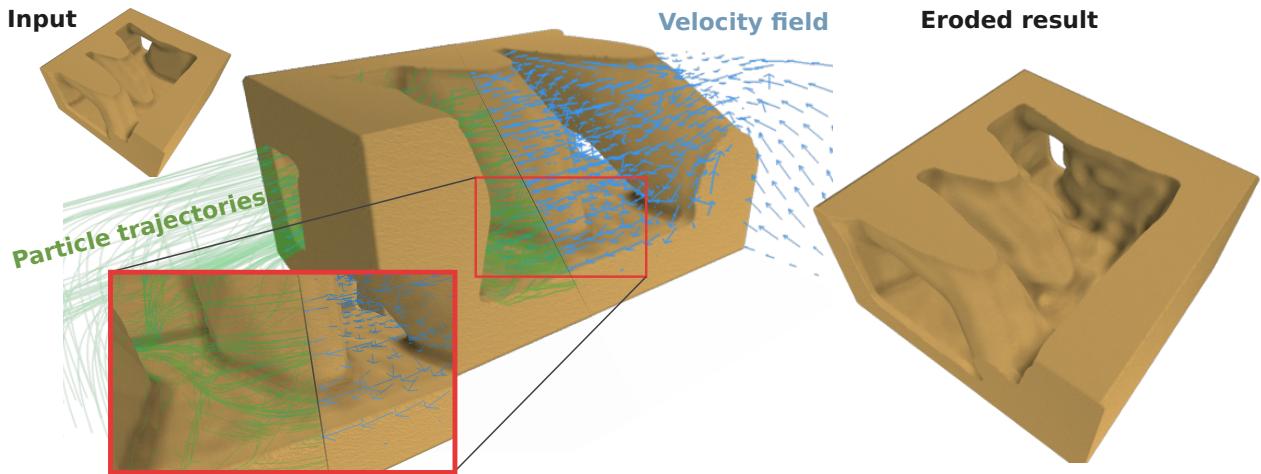

Figure 6.8: A complex water flow simulation is computed using OpenFOAM. Particle trajectories (green) are highly affected by the fluid velocity (blue). Most the terrain exposed surfaces is eroded (bottom).

while the coasts of the river are being eroded thanks to a velocity field defined at the water level. The velocity field defined in the air mainly affects particles with air-density, such that wind erosion can be applied at the same time. The computation of these effects took 7 seconds on CPU.

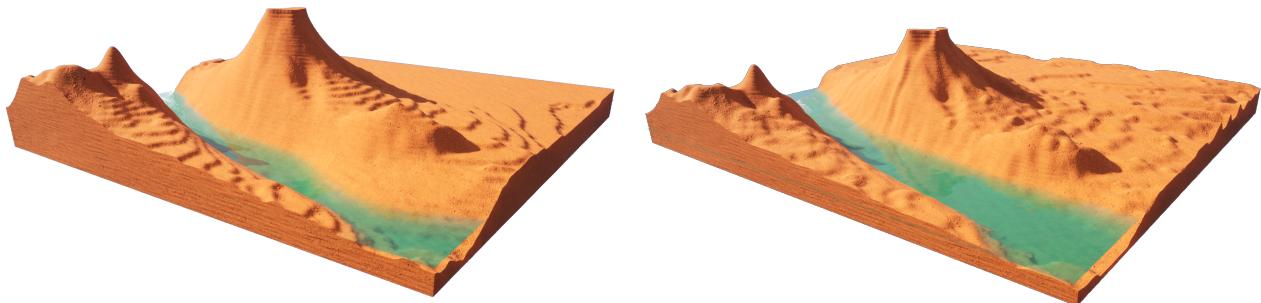

Figure 6.9: Multiple erosion types can be combined. On an initial synthetic 500x500x50 density voxel grid, the a wind erosion is applied on the surface of the terrain while hydraulic erosion shapes the rills and the base of the mountains. A water current digs its borders and spreads sediments at the bottom.

## 6.6 Comparisons

In the following section, we compare our method with existing ones to show that while we are versatile on the terrain representation, we are also able to reproduce various effects without applying specific algorithms. The other works are displayed in blue to distinguish them from ours.

Figure 6.10: The algorithm proposed by ( Paris et al., 2019b) allows for the simulation of coastal erosion (left) that we can reproduce almost identically by allowing our particles to collide only once with the ground and applying only erosion (center). If we apply our erosion with the full tracking of our particles and using deposition, we can achieve more diverse results (right).

### 6.6.1 Coastal erosion on implicit terrain representation

Paris et al., *Terrain Amplification with Implicit 3D Features* (2019) present an erosion simulation method applied to implicit terrains able to create coastal erosion, karsts and caves by adding negative sphere primitive in the terrain's construction tree. The positions of the spheres are determined using a Poisson disk sampling at the weakest terrain area defined by the Geology tree of their model. They are simulating the corrosion effect of water on the rocks. Our work is also able to approximate this phenomena by defining the position of these sphere primitives at the position where the water particles hit the surface. While the computation time of the positions of the sphere is higher due to the fact that we are evaluating the position of our particles at every time step in the implicit model (which could be improved by the triangulation of the implicit surface, or better, a dynamic triangulation), the distribution of our erosion primitives is based on a physical model instead of a mathematical model, meaning that we can integrate more easily the direction and strength of the waves for example. The management of their sphere primitives can be replicated with our method by considering that a particle exists until a collision occurs, at which point it disappears. Their method is not conserving the mass of the terrain, which is acceptable for the corrosion simulation, but limits its validity for other erosion simulations. In our method, the particle can be tracked until it settles, ensuring mass conservation (Figure 6.10);

### 6.6.2 Wind erosion on voxel grid representation

Beardall et al., *Directable weathering of concave rock using curvature estimation* (2010) propose a weathering erosion on voxel grids by approximating and eroding continuously the most exposed voxels. When a solid voxel is decimated, it is considered deposit and is displaced down the slope until a minimal talus angle in the terrain is reached and if the deposition is eroded again, it disappears. Our work is able to reproduce their algorithm by sending our particles from a close distance to the terrain surface. By doing so, we reproduce the erosion process as much as the deposition process since the air particles, filled with sediments, is falling automatically towards the local minimum of the erosion point. Just like in their work, we can easily define the resistance value of the materials to add diversity in the results. By adding the possibility of a wind field, even a very simple uniform vector field, to the simulation, we naturally add the wind shadowing effect that protects a gobelin surrounded by bigger gobelins, and also allows the deposit slope to fit more closely to the wind direction (Figure 6.11).

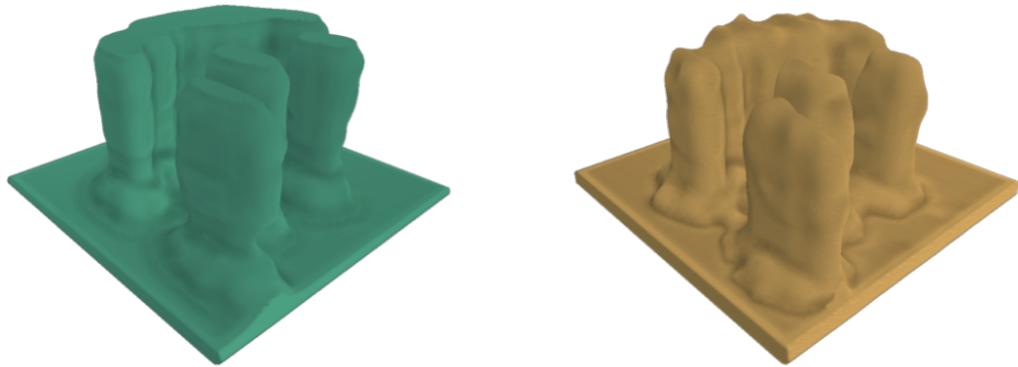

Figure 6.11: The algorithm proposed by ( Beardall et al., 2010) allows for an efficient simulation of the spheroidal erosion, making the creation of gobelins on voxel grids in a plausible way (left). Our algorithm naturally erodes the most exposed areas of the terrain when particles are affected by the wind (right).

### 6.6.3 Hydraulic erosion on height field representation

Mei et al., *Fast hydraulic erosion simulation and visualization on GPU* (2007) integrate and adapt to the GPU the pipe model proposed in ( O'Brien and Hodgins, 1995) for the fluid simulation. This simulation is simple but efficient enough to approximate the Shallow-Water equations in real time and use the speed of columns of water to compute the erosion and deposition rate on the 2D grid of the terrain at each time step. Using columns of water even allows the flow to overpass small bumps on the terrain over time. Our method initially rely on a stable fluid flow that is consistent during the whole life time of a particle, but by refining the simulation at each time step instead of at the end of the particles lifetime, our erosion model is able to reproduce this effect, allowing the terrain to have a single batch of fluid going through it. Our method can be seen as a generalization of Mei et al. that can then be used on more than discrete 2D grids (Figure 6.12).

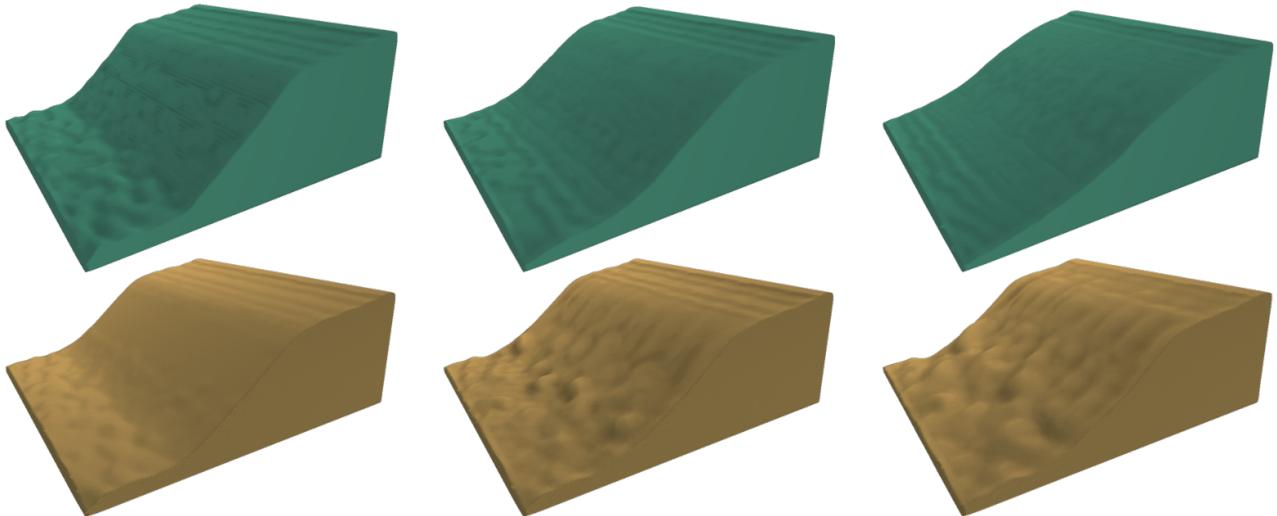

Figure 6.12: While our resulting geometry on the hydraulic erosion (bottom) is less smoothed than the one proposed proposed by ( Mei et al., 2007) (top), our method allows the application on more terrain representations than the height fields only.

### 6.6.4 Wind erosion on stacked materials representation

Paris et al., *Desertscape Simulation* (2019) simulate the effect of wind over sand fields defined on stacked materials, creating dune structures, even taking into account obstacles like ( Roa and Benes, 2004) and different material layers like vegetation ( Cordonnier et al., 2017a) that are not affected by abrasion( Paris et al., 2019a). A wind field simulation is required to produce results, and while ( Roa and Benes, 2004) and ( Onoue and Nishita, 2000) consider a uniform vector field, this work consider a dynamic vector multi-scaled warped field from the terrain height. The sand grains then apply multiple moves: sand lift, bounces, reptation and avalanching. Once the sand is lifted by the wind, the trajectory of the grains can be seen as the displacement of particles, fitting completely with our model as illustrated Figure 6.13.

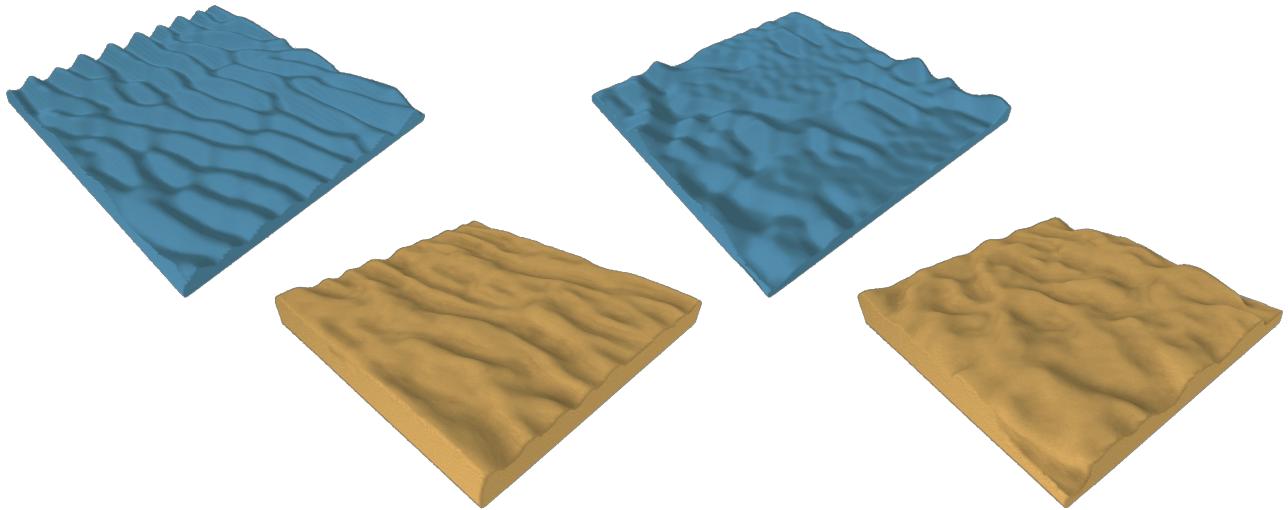

Figure 6.13: The algorithm from Paris 2020 allow the generation of desertscape (top), which we can (at least partially) reproduce with our erosion simulation (bottom). The different effects are achieved by affecting the wind direction and strength.

## 6.7 Discussion

This work is a generalization of erosion that is applicable to any terrain representation. In practice, while similar particle physics is used on different terrain representations, using similar parameters does not ensure resulting in the same eroded terrain. Surfaces and normals being approximated differently have rippling effect on particle trajectories. Note that, not all effects can be applied to all representations, for instance, karsts generation on 2.5D data structures.

### 6.7.1 Realism

Realism of the erosion simulation is highly correlated to the size and quantity of particles used and their distribution. Using too few or distributing them too sparsely will result in a terrain that is unrealistic since the alteration will have localized effects, breaking process homogeneity.

The resolution is also limited by the number and size of the particles, which can be problematic on implicit terrains that can theoretically have a infinite resolution.

Our method allows to perform erosion on implicit terrains. However, in its current form, our algorithm is time expensive on implicit representations since a large number of primitives are added in the composition tree. Using skeletons-defined primitives ( Hong, 2013; Rigaudi  re et al., 2000) from particles trajectories and erosion/deposition values could be a solution to optimize the computation time.

### 6.7.2 Usage of velocity fields

In our erosion algorithm, we simplify particle physics to enhance computational efficiency and facilitate parameterization. We use the velocity field from fluid simulations to approximate particle velocities. Sediment mass is harnessed to compensate for this approximation, allowing compatibility with various fluid simulation algorithms. Velocity fields can be recomputed at a frequency meeting the applications needs, ranging from "classic erosion simulation" (recomputed at each time step) to "simple simulation" (never recomputed). We addressed provisional adjustments to mitigate discrepancies when terrain changes due to erosion are not reflected in a static velocity field in section "3.3 Transport". However, it is important to note that these are expedient solutions and may not fully capture precise dynamics of an evolving terrain.

### 6.7.3 Performances

To facilitate parallelization, we intentionally overlook particle interactions and sediment exchanges, albeit at the expense of achieving smoother results. Surface collisions are simplified to basic bounces with a damping parameter instead of relying on complex particles and ground properties (Young's modulus, friction, material, ...)( Yan et al., 2020), further easing the parameterization process. However, these simplifications, combined with the inherent discrete nature of particles, as opposed to the continuous nature of erosion, result in a correlation between realism and particle count.

The performance of our method is influenced by the time required for collision detection. Consequently, we mainly observe better performances with explicit terrain models than with implicit models.

#### Particle's atomicity

While we can replicate various effects, the "fan" shape commonly observed in natural erosion patterns is not perfectly represented. This limitation arises because we do not account for the splitting of a particle, a process that significantly influences the multidirectional dislocation and trajectory of individual particles ( Ranz et al., 1960). Additionally, we acknowledge an issue where particles may collide with the ceiling and the deposition is stuck. While a potential resolution involves splitting particles upon impact rather than simply depositing sediments, this introduces complexities to the parallelization layer of the method. Allowing particles to split introduces unpredictability in the total number of particles that will exist in the simulation. This unpredictability can complicate the use of multi-threading. Future works includes finding a data structure allowing this splitting efficiently, leading to more realistic erosion patterns.

#### Simulation with multiple materials

One aspect we haven't addressed is a layered terrain with multiple materials. In the native way our method is done, we do not consider the transport of different materials (all sediments

are considered as sand), but by storing a list of the different materials and the quantity transported by each particle, the same simulation process could be done at the cost of some memory and performance overhead.

Another possible adaptation of the erosion strategy for material voxels is to extend the erosion computation from binary voxels by define transformation rules from one material to another when a voxel is eroded a number  $\#hits < -C$  or  $\#hits > C$ . For example, the material "clay" may transform to "sand" when eroded or to "rock" when many depositions occurred.

## 6.8 Conclusion

We introduced a flexible particle-based erosion system that is easy to use and simple to implement. We have presented how to adapt the process for various terrain representations and generate a variety of erosion phenomenon due to rain, wind, water bodies... by adjusting intuitive parameters hence generate automatically realistic 2.5D and 3D terrains. The use of external velocity fields provides a high flexibility i.e. using the simulations that best fits the user's needs (precision, control, implementation efficiency...). Our method can also be applied to underwater environments with identical physics simulation since our erosion method can be applied on 3D representations. Erosion algorithms are often limited to the use of height fields, but by finding more generalized methods, we can go toward a global use of 3D terrains, which can offer richer and more diverse landscapes.

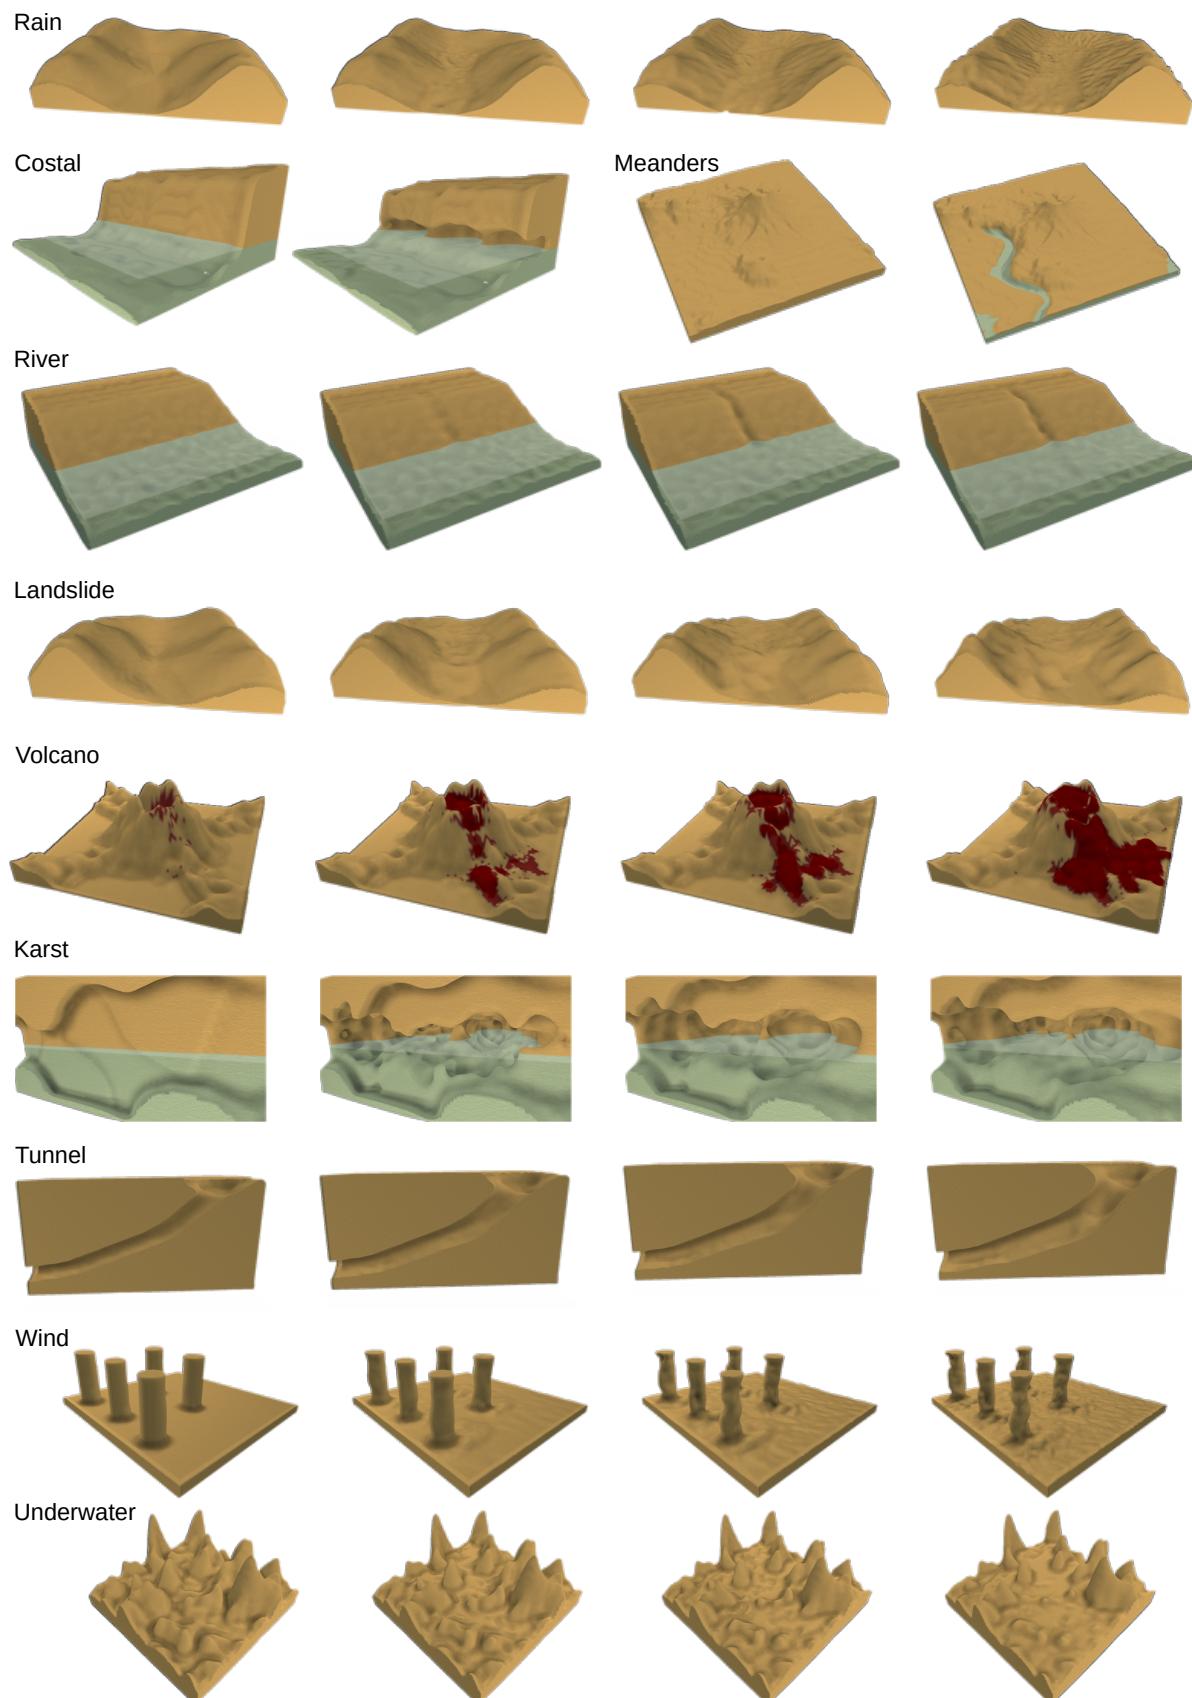

Figure 6.14: Erosion processes results on various representations presented in section 6.5. Used parameters used are detailed in Table 6.1.

## Glossary

---

**Coarse height function** Simplified function representing the height of a Semantic Terrain Entity in the 2D plane, useful to estimate the altitude of a point  $\mathbf{p}$  of the terrain  $\mathcal{H}(\mathbf{p})$  as a combination of the coarse height function of all Semantic Terrain Entities close to  $\mathbf{p}$ .. 28, 31, , 99

**Environmental attribute** Value of a geographic field at one point in space and time.. iv, 23, 26–29, 31, 33, 38, , 99, 100

**Environmental modifier** Description of a modification of a environmental attribute around a Semantic Terrain Entity. It can represent the spread or the absorption of material around it, or the deformation of water currents.. iv, 23, 26–28, 31–34, 38, , 100

**Fitness function** Function affected to a Semantic Terrain Entity that, given the environmental attribute at a  $(x, y)$  position in the space, returns a score describing how well this Semantic Terrain Entity may survive.. iv, 23, 26–31, 34, 37, 38, , 99, 100

**Generation rule** Composed of a fitness function and skeleton fitting function, the optimisation of the generation rule of an Semantic Terrain Entity through the maximization of its components describe where and how new elements can be added to a semantic terrain.. 26, 27, 29, 31, , 99, 100

**Geomorphic event** Modification of a environmental attribute in an interval of time with or without spatial bounds.. 26, 27, 33–36, 38,

**Level of detail** Amount of graphical data or information displayed in a scene or image. Higher LOD means more detail, while lower LOD means less detail. This concept helps manage computational resources, where less important or distant objects have lower LOD to improve performance.. 11,

**Parameter space** Set of adjustable parameters that can be modified to control and influence the generation process of content or assets. These parameters can include properties like size, shape, density, or other relevant factors, depending on the specific procedural algorithm being used. By adjusting these parameters, creators can achieve a wide variety of outcomes and patterns, enabling the generation of diverse and customizable content such as textures, levels, or 3D models.. 8,

**Semantic Terrain Entity** Geographic feature represented sparsly which describe a landscape.  
We represent it with a skeleton, generation rules and environmental modifiers.. iv, 23,  
26–34, 36–39, , 99, 100, 107

**Skeleton** Simplified shape of a Semantic Terrain Entity, as it could be symbolized in a map:  
as a point, a curve or a region.. , 100

**Skeleton fitting function** Function affected to a Semantic Terrain Entity that, given the local  
environmental attribute and the shape of the skeleton of the Semantic Terrain Entity,  
returns a score describing how well this Semantic Terrain Entity fits. It may be seen as a  
refinement of the fitness function.. iv, 23, 28–30, , 99

**Steady state** A system is at steady state when internal properties do not change overtime  
once a dynamic equilibrium has been reached. The environmental modifiers emission  
from Semantic Terrain Entities can be seen as a thermodynamic system which achieve  
thermodynamic equilibrium over time..

## Data structures

---

- ...

### .1 3D grids

- In this manuscript, all 3D grids are defined as signed float32.
- Not optimal, especially for representing binary voxels (uses 32x more memory and computation than necessary), but flexible...
- Voxel grids stored as lists of sub-grids ("local modifications") to navigate undo-redo. Cell evaluation by summing sub-grids.
- ...

- ...

## .2 Points

- Defined in 3D space as  $(x, y, z)^T$ .
- When projected in 2D,  $z = 0$  is implicit.
- Represented in the manuscript as:  $\mathbf{p} \in \mathbb{R}^3$
- ...

## .3 Curves

- Parametric function  $C : [0, 1] \mapsto \mathbb{R}^3$ .
- Unless otherwise specified, use of Centripetal Catmull–Rom spline [CITE CATMULL 1974]:
- \*\* Let  $\mathbf{p}_i$  denote a point. For a curve segment  $C$  defined by points  $\mathbf{p}_0, \mathbf{p}_1, \mathbf{p}_2, \mathbf{p}_3$  and knot sequence  $t_0, t_1, t_2, t_3$ , the centripetal Catmull-Rom spline can be produced by:

$$C(t) = \frac{t_2 - t}{t_2 - t_1} B_1 + \frac{t - t_1}{t_2 - t_1} B_2 \quad (15)$$

where

$$B_1(t) = \frac{t_2 - t}{t_2 - t_0} A_1(t) + \frac{t - t_0}{t_2 - t_0} A_2(t) \quad (16)$$

$$B_2(t) = \frac{t_3 - t}{t_3 - t_1} A_2(t) + \frac{t - t_1}{t_3 - t_1} A_3(t) \quad (17)$$

$$A_1(t) = \frac{t_1 - t}{t_1 - t_0} \mathbf{p}_0 + \frac{t - t_0}{t_1 - t_0} \mathbf{p}_1 \quad (18)$$

$$A_2(t) = \frac{t_2 - t}{t_2 - t_1} \mathbf{p}_1 + \frac{t - t_1}{t_2 - t_1} \mathbf{p}_2 \quad (19)$$

$$A_3(t) = \frac{t_3 - t}{t_3 - t_2} \mathbf{p}_2 + \frac{t - t_2}{t_3 - t_2} \mathbf{p}_3 \quad (20)$$

and

$$t_{i+1} = \sqrt{(x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2 + (z_{i+1} - z_i)^2}^\alpha + t_i \quad (21)$$

where  $\alpha$  ranges from 0 to 1 for knot parameterization, and  $i = 0, 1, 2, 3$  with  $t_0 = 0$ . For centripetal Catmull-Rom spline, the value of  $\alpha$  is 0.5. When  $\alpha = 0$ , the resulting curve is the standard uniform Catmull-Rom spline; when  $\alpha = 1$ , the result is a chordal Catmull-Rom spline.

\*\* We will keep  $\alpha = 0.5$  for all the work in this manuscript, as it felt like a good compromise between smoothness and control on the curve. The value of  $\alpha$  has not been studied deeply.

- Advantages: Centripetal Catmull-Rom spline has several desirable mathematical properties compared to the original and other types of Catmull-Rom formulations. First, it will not form loops or self-intersections within a curve segment. Second, cusps will never occur within a curve segment. Third, it follows the control points more tightly. [COPY PASTE WIKIPEDIA]

- Additionally, we do not use "handles" (invisible control points) like for Bézier curves. At the cost of a little user control, I feel the use is simplified.

- The calculation of first and second derivatives (tangent and normal) is quick.

- ...

---

## Snake - Active Contour Model

---

We want to symbolize a dead coral area as a Semantic Terrain Entity "reef." To do this, the coral objects continuously deposit a quantity of "dead coral" material. This material, stored in a discrete scalar field, contains high intensities where a reef should supposedly exist. We need to draw a curve to represent this new object. The constraints of this curve are that it must pass through the points of highest intensity while maintaining a given length.

The Snake algorithm, or Active Contour Model, approaches this application. The algorithm proposes to give an energy to the curve, which then tries to minimize it through gradient descent.

The energy, in the initial paper, is defined by

$$E_{\text{snake}}^* = \int_0^1 E_{\text{snake}}(\mathbf{v}(s)) ds = \int_0^1 E_{\text{internal}}(\mathbf{v}(s)) + E_{\text{external}}(\mathbf{v}(s)) ds \quad (22)$$

The internal energy represents the properties of the curve while the external energy represents properties of the field it lies in. In the original paper they are described as:

$$E_{\text{internal}} = \alpha E_{\text{continuity}} + \beta E_{\text{curvature}} \quad (23)$$

$$E_{\text{external}} = \gamma E_{\text{image}} \quad (24)$$

The continuity cost  $E_{\text{continuity}}$ , originally defined as the minimization of the spacing between the points  $\left\| \frac{d\bar{\sigma}}{ds}(s) \right\|^2$ , does not make much sense in the discrete form of the algorithm. In its discrete form, we seek to maintain a regular interval between the points by applying  $E_{\text{continuity}} = (\tilde{d} - \|p_i - p_{i-1}\|)^2$  with  $\tilde{d}$  being the average distance between each point.

The curvature cost  $E_{\text{curvature}}$  seeks to minimize the oscillations of the curve and can thus be defined as the squared second derivative  $\left\| \frac{d^2\bar{\sigma}}{ds^2}(s) \right\|^2$ .

The discrete form  $E_{\text{curvature}}^* = \|p_{i-1} - 2p_i + p_{i+1}\|^2$  is not necessary with splines, due to their closed form.

The image cost  $E_{\text{image}}$  tries to attract the points of the curve to a local maximum of the image gradient. It is defined as  $E_{\text{image}} = -\|\nabla I\|$ .

We want to see our curve maintain a given length  $L$ . We then modify the formulation of the continuity cost to become  $E_{\text{continuity}} = (\tilde{l} - \|p_i - p_{p-1}\|)^2$  with  $\tilde{l} = \frac{L}{n-1}$ , knowing  $n$  is the number of vertices of the curve. Additionally, we want a curve that follows points of high intensity rather than the gradient, which leads to modifying the image cost  $E_{\text{image}} = -I$ .

The calculation of the gradient  $\nabla E_{\text{snake}}$  remains trivial in parts:

$$\frac{\partial E_{\text{image}}}{\partial p_i} = -\nabla I(p_i) \quad (25)$$

$$\frac{\partial E_{\text{curvature}}^*}{\partial p_i} = -\frac{2(p_{i-1} - 2p_i + p_{i+1})}{\|p_{i-1} - 2p_i + p_{i+1}\|} \quad (26)$$

$$\frac{\partial E_{\text{continuity}}^*}{\partial p_i} = 2(l - \|p_i - p_{i-1}\|) \cdot \frac{p_i - p_{i-1}}{\|p_i - p_{i-1}\|} \quad (27)$$

We then have

$$E_{\text{snake}} = \alpha(l - \|p_i - p_{i-1}\|)^2 + \beta\|p_{i-1} - 2p_i + p_{i+1}\|^2 - \gamma I \quad (28)$$

$$\nabla E_{\text{snake}} = 2\alpha(l - \|p_i - p_{i-1}\|) \cdot \frac{p_i - p_{i-1}}{\|p_i - p_{i-1}\|} - \beta \frac{2(p_{i-1} - 2p_i + p_{i+1})}{\|p_{i-1} - 2p_i + p_{i+1}\|} - \gamma \nabla I(p_i) \quad (29)$$

It should be noted that the calculation of  $E_{\text{continuity}}^*$  uses the distance  $\|p_i - p_{i-1}\|$ . For  $i = 0$ , the distance  $\|p_i - p_{i+1}\|$  is used.

If all the points of the curve are at a distance greater than  $l$ , the optimization will push each of these points to get closer to its predecessor. Point  $p_0$ , itself, will move very little, so the entire curve aligns towards point  $p_0$ . By using the distance to the successor  $\|p_i - p_{i+1}\|$ , the curve moves towards point  $p_N$ . It is then possible to converge towards the median point by alternating the use of the distance with the predecessor and with the successor, at the cost of slower convergence.

The active contour model algorithm is highly sensitive to the initial curve placement. In cases where a portion of the curve is in an area with a very low gradient on  $E_{\text{image}}$ , the vertices of the curve will simply optimize  $E_{\text{internal}}$ , resulting in a straight segment in a low-intensity area, while the rest of the curve optimizes correctly.

To mitigate this problem, we propose adapting the Snake algorithm into Caterpillar: throughout the gradient descent, the target length  $L$  is artificially reduced and then increased. In this way, a portion of the curve blocked in a region without possible optimization on external energy will be attracted by the optimized curve until it falls on a strong gradient. The dead portion can take the place of optimized vertices. By returning the target length  $L$  to its initial value, the optimization continues with fewer vertices in the dead zone. Repeating this process gradually brings all points into an optimizable area. However, a too-rapid change in the target length can prevent the vertices from optimizing  $E_{\text{external}}$  by amplifying  $E_{\text{internal}}$  too much. Additionally, this algorithm can lead to numerical errors and slower convergence.

---

## Computation of a metaball

---

We use the following formula to evaluate a metaball in space with a center  $c$  and of radius  $R$ :

$$g(\mathbf{p}) = 1 - \frac{\|\mathbf{p} - c\|}{R}$$

using the euclidean distance.

We have a total amount  $Q$  to define in this space, so the final metaball function  $f$  needs to satisfy the equations Equation (30) and Equation (31):

$$f(\mathbf{p}) = \lambda g(\mathbf{p}) \quad (30)$$

$$\int_{\mathbf{p} \in V_{3D}} f d\mathbf{p} = Q \quad (31)$$

First, let's exploit the radial symmetry of the metaball and rewrite  $g(\mathbf{p}) = 1 - r$  by using the polar coordinates of the point  $\mathbf{p} - c$ .

We can then integrate  $g$  over the volume  $V_{3D}$  as

$$\begin{aligned} & \int_0^1 \int_0^\pi \int_0^{2\pi} g(r)r^2 \sin(\theta) dr d\theta d\phi \\ &= \int_0^1 \int_0^\pi \int_0^{2\pi} (1-r)r^2 \sin(\theta) dr d\theta d\phi \\ &= \int_0^1 (1-r)r^2 dr \times \int_0^\pi \sin \theta d\theta \times \int_0^{2\pi} 1 d\phi \end{aligned}$$

We then break down the integrals one by one such as

$$\begin{aligned} \int_0^1 (1-r)r^2 dr &= \frac{1}{12} \\ \int_0^\pi \sin \theta d\theta &= 2 \\ \int_0^{2\pi} 1 d\phi &= 2\pi \end{aligned}$$

By combining all these integrals, we get  $\int g = \frac{1}{12} \times 2 \times 2\pi = \frac{\pi}{3}$ .

So given  $\int f = q_{\text{detachment}}$  and  $\int f = \lambda \int g$ , we can deduce that  $\lambda = \frac{Q}{\int g} = \frac{3}{\pi}Q$ .

From Equation (30) we finally get

$$f(\mathbf{p}) = \frac{3Q}{\pi} \left( 1 - \frac{\|\mathbf{p} - c\|}{R} \right) \quad (32)$$

, representing the rate of change on the evaluation function of the terrain surface.

The integration in the voxel space is out of the scope of this paper and a numerical solution is instead proposed in Section 6.4.4.

---

## Implicit terrains with materials

---

- Volumetric modeling is important for representing 3D structures
- Allows for the representation of cavities, arches, overlays, etc.
- The concept of materials allows for including much more information for the following parts: amplification and rendering
  - \*\* Amplification (e.g., erosion) needs to know the type of soil at the surface and subsurface to be realistic
  - \*\* Rendering needs to know the material at the surface to correctly display textures
- ...
